Appendix C, Commonly Used Medications, which appears in the back matter and in the book’s online materials, provides information about numerous drugs frequently used to treat children with disabilities. This appendix is in no way meant to substitute for a physician’s advice or expert opinion; readers should consult a medical practitioner if they are interested in more information.

The publisher and the authors have made every effort to ensure that all of the information and instructions given in this book are accurate and safe, but they cannot accept liability for any resulting injury, damage, or loss to either person or property, whether direct or consequential and however it occurs. Medical advice should only be provided under the direction of a qualified health care professional.

The vignettes presented in this book are composite accounts that do not represent the lives or experiences of specific individuals, and no implications should be inferred. In all instances, names and identifying details have been changed to protect confidentiality.

Purchasers of *Children with Disabilities, Eighth Edition*, are granted permission to download, print, and photocopy the Online Companion Materials for educational purposes. In addition, purchasers are granted permission to download Appendices A–D and the letters from Andrew Batshaw for research and professional purposes. PowerPoint presentations, illustrations, extended case studies, a test bank, and sample syllabi are also available for faculty. All Online Companion Materials are available at <http://downloads.brookespublishing.com/children-with-disabilities-8e>. This content may not be reproduced to generate revenue for any program or individual. Photocopies may only be made from the original content. *Unauthorized use beyond this privilege may be prosecutable under federal law.* You will see the copyright protection notice at the bottom of each page.

Library of Congress Cataloging-in-Publication Data

Names: Batshaw, Mark L., 1945- editor. | Roizen, Nancy J., editor. | Pellegrino, Louis, editor.

Title: Children with disabilities / edited by Mark L. Batshaw, M.D., Nancy J. Roizen, M.D., and Louis Pellegrino, M.D.

Description: Eighth edition. | Baltimore : Paul H. Brookes Publishing Co., [2019] | Includes bibliographical references and index.

Identifiers: LCCN 2018048552 (print) | LCCN 2018059190 (ebook) | ISBN 9781681253213 (epub) | ISBN 9781681253220 (pdf) |

ISBN 9781681253206 (hardcover)

Subjects: LCSH: Developmental disabilities. | Developmentally disabled children—Care. | Children with disabilities—Care.

Classification: LCC RJ135 (ebook) | LCC RJ135 .B38 2019 (print) | DDC 618.92/8588—dc23

LC record available at <https://lcn.loc.gov/2018048552>

Letters from Andrew Batshaw	xxxi

I As Life Begins

1 The Genetics Underlying Developmental Disabilities	
<i>Mark L. Batshaw, Eyby Leon, and Monisha S. Kisling</i>	3
Genetic Disorders.	4
Chromosomes.	4
Cell Division and Its Disorders	5
Genes and Their Disorders.	8
Epigenetics	17
Genetic Testing.	17
Environmental Influences on Heredity	19
Genetic Therapies.	20
2 Environmental Exposures	
<i>Shruti N. Tewar</i>	23
A Historical Perspective	24
The Developing Brain and Toxic Exposure	24
Timing of Vulnerability to Environmental Toxins	25
Specific Neurotoxicants.	25
Environmental Toxicants and Epigenetics.	31
The Societal Cost of Environmental Toxicants	31
Public Policy Implications.	32
3 Birth Defects and Prenatal Diagnosis	
<i>Rhonda L. Schonberg and Margaret B. Menzel</i>	37
Genetic Assessment and Carrier Detection	38
Screening Tests During Pregnancy.	40
Genetic Counseling and Decision Making	46
Decreasing the Risk of a Birth Defect.	46
Alternative Reproductive Choices.	46
Psychosocial Implications of Prenatal Testing.	49
4 Newborn Screening	
<i>Joan E. Pellegrino</i>	53
What Is a Screening Test?	53
Why Screen Newborns?	54

How Is Newborn Screening Done?	58
What Should Be Done When a Child Has a Positive Newborn Screen?	59
What Happens to Children with Confirmed Disease?	59
What Is the Risk of Developmental Disability in Children with Confirmed Disease?	60
How Can Screening Fail?	60
The Past, Present, and Future of Newborn Screening	61
5 Premature and Small-for-Dates Infants	
<i>Khodayar Rais-Bahrami and Billie Lou Short</i>	65
Definitions of Prematurity and Low Birth Weight	66
Incidence of Preterm Births	67
Causes of Premature Birth	67
Complications of Prematurity	69
Medical and Developmental Care of Low Birth Weight Infants	75
Survival of Low Birth Weight Infants	76
Care After Discharge from the Hospital	76
Early Intervention Programs	77
Neurodevelopmental Outcome	77
II The Child's Body: Physiology	
6 Fetal Development	
<i>Nickie N. Andescavage</i>	85
Overview of Key Anatomic Structures	86
Human Development	86
Placental Development and Function	90
Maternal, Fetal, and Placental Origins of Developmental Disorders	90
Evaluation of Fetal Development	94
Diagnostic Considerations	95
Overview of Management Strategies	95
7 The Senses: The World We See, Hear, and Feel	
<i>Louis Pellegrino</i>	99
The World We See	99
The World We Hear	104
The World We Feel	112
Sensory Integration and Motor Control	113
8 The Brain and Nervous System	
<i>Joseph Scafidi and Andrea Gropman</i>	119
The Brain and Spinal Cord	120
The Peripheral Nervous System	128
The Microscopic Architecture of the Brain	129
Techniques for Evaluating the Central Nervous System	131
9 Muscles, Bones, and Nerves	
<i>Peter B. Kang</i>	139
Overview of the Neuromuscular and Musculoskeletal Systems	140
Symptoms and Signs of Neuromuscular and Musculoskeletal Disorders	141
Laboratory Testing and Radiography	143
Disorders of the Neuromuscular System	144
Disorders of the Musculoskeletal System	149
Management Principles	151

10	Nutrition	
	<i>Lina Diaz-Calderon, Virginia Gebus, and Laurie S. Conklin.</i>	159
	Typical Growth During Childhood.	160
	Nutritional Guidelines	161
	Nutritional Issues in Children with Developmental Disabilities.	161
	Medical Nutritional Therapy	165
	Special Nutritional Concerns in Children with Disabilities	167
	Nutrition within Complementary Health Approaches	170
III	Developmental Assessment	
11	Child Development	
	<i>Louis Pellegrino.</i>	177
	Defining Child Development.	178
	Theoretical Perspectives on Development.	179
	Developmental Milestones.	181
	Development and Adaptation: Trends and Key Milestones	183
	Distinguishing Typical and Atypical Development.	194
12	Diagnosing Developmental Disabilities	
	<i>Scott M. Myers</i>	199
	Developmental Principles.	200
	Atypical Patterns of Development.	201
	Diagnostic Classification.	204
	The Diagnostic Process	208
13	Neuropsychological Assessment	
	<i>Lauren Kenworthy and Laura Gutermuth Anthony</i>	225
	The Purpose of Neuropsychological Assessment.	226
	A Model for Developmental Neuropsychological Assessment	226
	Domains of Functioning Assessed in Neuropsychological Evaluations.	229
	Ensuring That Assessment Informs Management	234
IV	Developmental Disabilities	
14	Intellectual Disability	
	<i>Bruce K. Shapiro and Mark L. Batshaw</i>	249
	Defining Intellectual Disability	250
	Classification of Intellectual Disability.	251
	Prevalence of Intellectual Disability	253
	Diagnosis and Clinical Manifestations.	255
	Medical Diagnostic Testing	256
	Psychological Testing.	257
	Comorbid/Associated Conditions	257
	Treatment, Management, and Interventions	258
	Outcome	261
15	Down Syndrome and Fragile X Syndrome	
	<i>Elizabeth Berry-Kravis, Katherine Myers, and Nancy J. Roizen</i>	265
	Down Syndrome	266
	Fragile X Syndrome	274

16	Inborn Errors of Metabolism	
	<i>Nicholas Ah Mew, Erin MacLeod, and Mark L. Batshaw</i>	285
	Types of Inborn Errors of Metabolism	286
	Mechanism of Brain Damage	291
	Associated Disabilities	291
	Diagnostic Testing	291
	Newborn Screening	292
	Therapeutic Approaches	292
	Outcome	297
17	Speech and Language Disorders	
	<i>Barbara L. Ekelman and Barbara A. Lewis</i>	301
	Definitions, Descriptions, and Classifications	302
	Prevalence and Epidemiology	307
	Etiology	309
	Assessment and Diagnosis	311
	Treatment, Management, and Intervention	312
	Outcomes	313
18	Autism Spectrum Disorder	
	<i>Deborah Potvin and Allison B. Ratto</i>	317
	Definitions, Description, and Classifications	319
	Developmental Course of Autism Spectrum Disorder	323
	Prevalence and Epidemiology	324
	Etiology: Causes of Autism Spectrum Disorder	326
	Diagnosis and Assessment	329
	Associated Conditions	331
	Treatment, Management, and Interventions	334
	Outcomes	337
19	Attention-Deficit/Hyperactivity Disorder	
	<i>Marianne M. Glanzman and Neelam Kharod Sell</i>	347
	Diagnosis and ADHD Presentations	348
	Prevalence and Epidemiology	350
	Clinical Presentation	351
	Common Coexisting Conditions	352
	Associated Impairments	353
	Causes of ADHD	355
	The Evaluation Process	358
	Treatment of ADHD	359
	Treatment with Coexisting Conditions	369
	Alternative Therapies	371
	Outcome	373
20	Specific Learning Disabilities	
	<i>Robin P. Church and M.E.B. Lewis</i>	395
	Defining Learning Disorders	397
	Prevalence	401
	Etiology: Biological and Environmental Factors	401
	Classifying Learning Disorders	402
	Impairments Associated with Specific Learning Disabilities	405
	Health Problems Simulating Specific Learning Disabilities	407
	Additional Challenges in the School Setting	408

Assessment Procedures	408
Intervention Strategies	409
Outcome	414
21 Cerebral Palsy	
<i>Tara L. Johnson, Eric M. Chin, and Alexander H. Hoon</i>	423
What Is Cerebral Palsy?	424
What Causes Cerebral Palsy?	424
Epidemiology	426
Risk Factors	426
Diagnosis	427
Subtypes of Cerebral Palsy	434
Establishing the Etiology of Cerebral Palsy	436
Associated Impairments in Cerebral Palsy	436
Comprehensive Management for Individuals with Cerebral Palsy	437
Advocacy and Awareness	449
Future Directions	449
22 Epilepsy	
<i>Tesfaye Getaneh Zelleke, Dewi Frances T. Depositario-Cabacar, and William Davis Gaillard</i>	457
Epilepsy: Definitions and Classification	458
Diagnosis and Evaluation	467
Treatment	469
Multidisciplinary Care	473
Outcome	474
23 Acquired Brain Injury	
<i>Sarah Risen, Scott C. Schultz, and Melissa K. Trovato</i>	481
Overview of Traumatic Brain Injury	483
Severity of Traumatic Brain Injury	485
Nontraumatic Acquired Brain Injury	490
Rehabilitation and Outcomes	494
Prevention	497
24 Developmental Disability in Chronic Disease	
<i>Nancy J. Roizen and Catherine Scherer</i>	507
Sickle Cell Disease	508
Congenital Heart Disease	510
Chronic Kidney Disease	514
Acute Lymphocytic Leukemia and Brain Cancer	516
V Associated Disabilities	
25 Visual Impairment	
<i>Heather de Beaufort</i>	525
Definitions, Descriptions, and Classifications	526
Prevalence and Epidemiology	528
Visual Deficit in Children with Disabilities	528
Etiology and Associations with Specific Developmental Disabilities	528
Diagnosis and Clinical Manifestations	531
Monitoring, Screening, and Evaluation	534
Treatment, Management, and Interventions	534
Outcomes	539

26	Deaf/Hard of Hearing Plus	
	<i>Susan E. Wiley</i>	541
	Definitions, Descriptions, and Classifications	542
	Prevalence and Epidemiology	542
	Causes and Associations with Specific Developmental Disabilities	545
	Diagnosis and Clinical Manifestations	546
	Monitoring, Screening, and Evaluation	549
	Treatment, Management, and Interventions	549
	Outcomes	549
27	Behavioral and Psychiatric Disorders	
	<i>Adelaide S. Robb and Gabrielle Sky Cardwell</i>	555
	Prevalence of Psychiatric Disorders Among Children with Developmental Disabilities	556
	Causes of Psychiatric Disorders in Developmental Disabilities	557
	Psychiatric Disorders of Childhood and Adolescence	558
	Vulnerability	567
	Evaluation	567
	Treatment	568
28	Sleep Disorders	
	<i>Judith Owens and Miriam Weiss</i>	583
	Sleep Architecture	583
	Sleeping Patterns	584
	Insomnia	584
	Circadian Rhythm Disorders	588
	Disorders of Arousal/Partial Arousal Parasomnias	590
	Sleep-Disordered Breathing and Obstructive Sleep Apnea	593
	Movement Disorders in Sleep: Restless Leg Syndrome, Periodic Limb Movement Disorder, and Sleep-Related Rhythmic Movement Disorder	596
29	Feeding and Its Disorders	
	<i>Peggy S. Eicher</i>	601
	The Feeding Process	602
	Prevalence and Epidemiology	607
	Etiology and Associations with Specific Developmental Disabilities	607
	Diagnosis and Clinical Manifestations	611
	Monitoring, Screening, and Evaluation	614
	Treatment, Management, and Interventions	615
	Outcomes	620
VI	Interventions	
30	Interdisciplinary Education and Practice	
	<i>Lewis H. Margolis and Angela McCaffrey Rosenberg</i>	627
	Defining Interdisciplinary Education and Practice	628
	The Growth and Development of Interdisciplinary Practice	631
	Measuring the Effects of Interdisciplinary Education and Practice	632
	Implementing and Sustaining Interdisciplinary Education and Practice	633
31	Early Intervention Services	
	<i>Toby M. Long</i>	639
	Principles of Early Intervention	640
	Research Support for the Value of Early Intervention	640
	Prevalence and Epidemiology	640

	Components of Part C of IDEA: The Infants and Toddlers with Disabilities Program.	640
	Outcomes.	646
32	Rehabilitative Services	
	<i>Melissa Fleming, Marisa Birkmeier, Mackenzie Brown, Justin M. Burton, Satvika Garg, and Sarah H. Evans</i>	649
	Principles and Processes of Functional Assessment.	650
	Principles of Treatment.	655
33	Special Education Services	
	<i>Elissa Batshaw Clair</i>	667
	Prevalence and Epidemiology	669
	Goals of Treatment: The Individualized Education Program.	673
	Treatment, Management, and Interventions	677
	Services Provided by Special Education Teachers	680
	The Role of the Special Education Teacher in the General Education Curriculum	680
	The School–Parent Connection	681
	Outcomes.	682
34	Behavioral Therapy	
	<i>Henry S. Roane, William E. Sullivan, Brian K. Martens, and Michael E. Kelley.</i>	687
	Operant Conditioning.	689
	Measurement and Data Analysis in Behavioral Treatments.	691
	Behavioral Treatment of Challenging Behavior	693
35	Oral Health	
	<i>Erik Scheifele, Mitali Y. Patel, Anupama Rao Tate, and H. Barry Waldman</i>	705
	Oral Development	706
	Oral Diseases	707
	Malocclusion.	708
	Oral Trauma	708
	Contributing Factors to Oral Conditions of Individuals with Disabilities	709
	Prevention of Dental Caries and Periodontal Disease	710
	The Dental Home	711
	Special Issues in Dental Care for Children with Specific Developmental Disabilities	711
	The Challenge of Providing Dental Services to Individuals with Disabilities.	713
36	Assistive Technology	
	<i>Larry W. Desch.</i>	719
	Technology for Medical Assistance.	721
	Technology for Physical Disabilities.	724
	Technology for Sensory Impairments.	725
	Technology for Communication Disabilities.	725
	Technology for Cognitive and Learning Disabilities.	726
	Assessment for Assistive Technology.	726
	Effects of Assistive Technology on the Family and Community	728
	Funding Issues	729
	Advocacy Information.	730
37	Family Assistance	
	<i>Michaela L. Zajicek-Farber</i>	735
	Understanding Family Systems.	737
	How Families Cope with the Diagnosis.	739
	Long-Term Effects on the Parents	742
	Effects on Siblings	744
	Effects on the Extended Family	745

	Effects on the Child with a Disability	745
	Principles of Family-Centered Care: Role of the Professional	749
	The Role of Society and Community	750
38	Pharmacological Therapy	
	<i>Shogo John Miyagi and Johannes N. van den Anker</i>	759
	The Role of Medications	760
	When to Start Medications	760
	Factors Affecting Drug Concentrations	761
	Factors Affecting Drug Administration	763
	Other Factors to Consider	765
39	Complementary Health Approaches	
	<i>Thomas D. Challman</i>	771
	History, Definitions, and Descriptions	772
	Treatment, Management, and Interventions	772
VII	Outcomes	
40	Transition from Adolescence to Adulthood	
	<i>Lisa K. Tuchman and Cara E. Pugliese</i>	781
	General Principles of Transition to Adulthood	782
	Moving Toward Independence: Neurodiversity, Self-Advocacy, and Self-Determination	782
	Moving from School to Work	783
	Moving from Home into the Community	788
	Moving from Pediatric- to Adult-Oriented Health Care	790
41	Medical Home and Health Care Systems	
	<i>Renee M. Turchi and Angelo P. Giardino</i>	799
	Health Care Utilization	800
	The Concept of the Medical Home	802
	The Importance of Coordination of Care	804
	Changes in Financing Health Care for CYSHCN	809
42	Racial and Ethnic Disparities	
	<i>Olanrewaju O. Falusi, Monika Goyal, Elissa Batshaw Clair, Catherine Larsen Coley, Susan Keller, Mary A. Hadley, and Denice Cora-Bramble</i>	823
	Definitions	823
	Racial and Ethnic Health Disparities in Children with Disabilities	825
	Racial and Ethnic Disparities in Special Education	826
	Etiologies and Federal Initiatives	829
	Reducing Disparities: Considerations for Clinicians and Educators	830
Appendix A	Glossary	837
Appendix B	Syndromes and Inborn Errors of Metabolism	
	<i>Kara L. Simpson</i>	873
Appendix C	Commonly Used Medications	
	<i>Dimitrios A. Savva, Shogo John Miyagi, and Johannes N. van den Anker</i>	917
Index		939

About the Online Companion Materials

All readers can access Online Companion Materials, which supplement and expand upon the content, the knowledge, and the resources offered in this text.

Please visit **<http://downloads.brookespublishing.com/children-with-disabilities-8e>** to access the following:

- Appendices A, B, and C in digital form
- Appendix D, a resource directory of national organizations, federal agencies, information sources, self-advocacy and accessibility programs, and support groups that provide assistance to families and professionals
- Study questions and extension activities for every chapter to help readers check and expand their knowledge of key concepts
- Letters from Andrew Batshaw, spanning all eight editions of the book

About the Online Companion Materials for Faculty

Attention instructors! Online Companion Materials are available to help you teach a course using *Children with Disabilities, Eighth Edition*.

Please visit <http://downloads.brookespublishing.com/children-with-disabilities-8e> to access the following:

- Customizable PowerPoint presentations for every chapter, totaling over 450 slides
- All original illustrations from the book, downloadable for easy use in your PowerPoint presentations, tests, handouts, and other course purposes
- Study questions for every chapter to help students check their knowledge of key concepts
- Extension activities for class use, group projects, and homework to help students apply the information from the text
- A test bank with more than 200 multiple-choice, fill-in-the-blank, and essay questions for instructors to use and adapt in course exams
- Extended case studies to enrich discussions of how concepts are interconnected
- Sample syllabi from various fields to help you determine what chapters and sequence best suits the needs of your course
- Letters from Andrew Batshaw, spanning all eight editions of the book
- Appendix D: Childhood Disabilities Resources, Services, and Organizations

About the Editors

Mark L. Batshaw, M.D., holds the “Fight for Children” Chair of Academic Medicine and is Chief Academic Officer, and Physician-in-Chief at the Children’s National Medical Center (CNMC) in Washington, D.C. He is also Professor of Pediatrics at George Washington University School of Medicine and Health Sciences in Washington, D.C.

Dr. Batshaw is a board-certified neurodevelopmental pediatrician who has treated children with developmental disabilities for more than 40 years. In 2006, Dr. Batshaw received both the Capute Award for notable contributions to the field of children with disabilities by the American Academy of Pediatrics and the Distinguished Research Award from The Arc. In 2015, he received the C. Anderson Aldrich Award in Child Development from the American Academy of Pediatrics.

Before moving to Washington in 1998, Dr. Batshaw was Physician-in-Chief of Children’s Seashore House, the child development and rehabilitation institute of The Children’s Hospital of Philadelphia. He is a graduate of the University of Pennsylvania and the University of Chicago Pritzker School of Medicine. Following pediatric residency at the Hospital for Sick Children in Toronto, he completed a fellowship in developmental pediatrics at the Kennedy Krieger Institute at The Johns Hopkins Medical Institutions.

Dr. Batshaw continues to pursue his research on innovative treatments for inborn errors of metabolism, including gene therapy. He has published more than 150 articles, chapters, and reviews on his research interests and the medical aspects of caring for children with disabilities. Dr. Batshaw was the founding editor-in-chief (1995–2001) of the journal *Mental Retardation and Developmental Disabilities Research Reviews*.

Dr. Batshaw lives in Washington, D.C. He and his wife Karen, a novelist, have three children and nine grandchildren.

Nancy J. Roizen, M.D., is Chief of the Division of Developmental-Behavioral Pediatrics and Psychology at University Hospitals Rainbow Babies and Children’s

Hospital in Cleveland and Professor of Pediatrics, Case Western Reserve University. She is certified in neurodevelopmental disabilities and developmental-behavioral pediatrics.

Dr. Roizen received her B.S. and M.D. degrees from Tufts University. After completing an internship in pediatrics at Massachusetts General Hospital, she did a residency in pediatrics at The Johns Hopkins Hospital. Her fellowships were in neurodevelopmental disabilities at the Kennedy Krieger Institute and in developmental and behavioral pediatrics at University of California, San Francisco. She was then a staff physician at the Child Development Center at Oakland Children’s Hospital for 8 years, followed by 16 years as Chief of the Section of Developmental Pediatrics at University of Chicago. Next, at SUNY Upstate Medical University, she was Vice Chair for Education for the Department of Pediatrics and Chief of the Division of Neurosciences for 4 years. Next stop was the Cleveland Clinic, where she was the Chief of the Department of Developmental Pediatrics and Psychiatry for 2 years. Dr. Roizen has published 125 articles, books, reviews, and chapters on research and the clinical aspects of children with developmental disabilities, including those with Down syndrome, toxoplasmosis, and velocardiofacial syndrome.

Dr. Roizen lives in Shaker Heights, Ohio, with her husband. They have two children and one granddaughter.

Louis Pellegrino, M.D., is Associate Professor of Pediatrics at SUNY Upstate Medical University, in Syracuse, New York. He is the director of the Child Development Program in the Center for Development, Behavior, and Genetics at Upstate Golisano Children’s Hospital in Syracuse, New York.

Dr. Pellegrino is board-certified in neurodevelopmental disabilities and developmental-behavioral pediatrics and has been working with children with developmental disabilities for over 25 years. He is a graduate of the University of Connecticut School of Medicine, received his pediatric residency training at Upstate

Medical University, and completed a fellowship in developmental pediatrics at the University of Rochester.

Dr. Pellegrino was a co-editor of the sixth edition of *Children with Disabilities* and is the author of *The Common Sense Guide to Your Child's Special Needs: When to Worry, When to Wait, What to Do* (Paul H. Brookes Publishing Co., 2012), a companion volume to *Children with Disabilities* that was written for caregivers.

Dr. Pellegrino lives in Syracuse, New York, with his wife Joan, an accomplished medical geneticist and fellow author in this book. They have two children: Elizabeth, who is studying science writing and creative nonfiction, and Nicholas, who is studying computer science. Dr. Pellegrino is an avid gardener who loves all things green and growing.

Washington, DC 20010

A Personal Note to the Reader

As it enters its eighth edition, *Children with Disabilities* has continued to evolve. The first edition was derived from lectures I gave for a special education course at The Johns Hopkins University School of Education in Baltimore in 1978. The book contained 23 chapters, and I authored or co-authored virtually all of them. When I started writing the first edition, I was 3 years out of my neurodevelopmental disabilities fellowship training program, and I thought I knew everything about developmental disabilities! I also considered myself an expert in my own children's development, having just welcomed into our family our third child, Andrew (Drew).

With this new edition of the book, the number of chapters and pages has basically tripled since its inception, and I have authored but a few chapters. I have recognized the need for additional help and counsel and have brought on two valued colleagues, Dr. Louis Pellegrino and Dr. Nancy J. Roizen, to coedit the book with me. Lou directs the Child Development Program in the Center for Development, Behavior, and Genetics at Upstate Golisano Children's Hospital in Syracuse, New York. My friendship with Nancy, Division Chief of Pediatric Developmental and Behavioral Psychology at University Hospitals Rainbow Babies and Children's

Hospital in Cleveland, Ohio, dates back to our training together at Hopkins. Based on our individual areas of expertise, we divided the book up. I took the sections *As Life Begins*, *The Child's Body: Physiology, and Outcomes*; Lou focused on *Developmental Assessment and Developmental Disabilities*; and Nancy edited the sections on *Associated Disabilities and Interventions*.

The book has also become somewhat of a family affair. My daughter Elissa, a special education teacher and school psychologist, authored the chapter on *Special Education Services* and contributed to the chapter on *Racial and Ethnic Disparities*. And Drew has continued his autobiographical letters concerning the effect of attention-deficit/hyperactivity disorder on his life, with him now being a successful executive in a start-up company and father to Mika and Gia.

It has been both personally and professionally very rewarding to develop this book over the past 40 years. Many of those rewards have come from the students, colleagues, and parents who have shared with me their thoughts and advice about the book. It is my hope that *Children with Disabilities* will continue to fill the needs of its diverse users for many years to come.

Mark L. Batshaw

Preface

One of the first questions asked about a subsequent edition of a textbook is, “What’s new?” The challenge of determining what to revise, what to add, and, in some cases, what to delete is always significant in preparing a new edition in a field that is changing as rapidly as developmental disabilities. Since the publication of the seventh edition in 2013, advances in the fields of neuroscience and genetics have greatly enhanced our understanding of the brain and inheritance. This creates opportunities for treatments previously not thought possible for some children with developmental disabilities. Genomic sequencing is now used routinely (and sometimes recreationally), gene therapy is being used to correct birth defects, and the brain can be probed noninvasively by functional imaging techniques.

The need to examine and explain this advanced knowledge and its significance for children with disabilities has necessitated an increase in the depth and breadth of the subjects covered in the book. Yet, although the book is now more expansive and has several new chapters, we have worked hard to ensure that it retains its clarity and cohesion. Its mission continues to be to provide the individual working with and caring for children with disabilities the necessary background to understand different disabilities and their treatments, thereby enabling affected children to reach their full potential.

THE AUDIENCE

Since it was originally published, *Children with Disabilities* has been used by students in a wide range of disciplines as a medical textbook addressing the impact of disabilities on child development and function. It has also served as a professional reference for special educators, general educators, physical therapists, occupational therapists, speech-language pathologists, psychologists, child-life specialists, social workers, pediatric residents and medical students, psychiatrists, neurologists, pediatric nurses and nurse practitioners, advocates, and other practitioners who provide care for children with disabilities. Finally, as a family resource, parents, grandparents, siblings, and other family members and friends

have used the book. They have found useful information on the medical and rehabilitative aspects of care for the child with developmental disabilities.

FEATURES FOR THE READER

We have been told that the strengths of previous editions of this book have been the accessible writing style, the clear illustrations, and the up-to-date information and references. We have dedicated our efforts to retaining these strengths and building on them with the addition of new features to highlight the application of content to evidence-based practice. Some of the features you will find in the eighth edition include the following.

- *Learning goals:* Each chapter begins with learning outcomes to orient you to the key content of that particular chapter.
- *Thought questions:* Questions have been crafted to “prime” the reader for what he or she should be thinking about while reading the chapter.
- *Case studies:* Most chapters include one or more situational examples to help bring alive the conditions and issues discussed in the chapter.
- *Key terms:* As key medical terms pertaining to a specific chapter are introduced in the text, they appear in boldface type at their first use; definitions for these terms appear in the Glossary (Appendix A).
- *Illustrations and tables:* More than 200 drawings, photographs, radiographs, imaging scans, and tables reinforce important concepts and provide ways for you to more easily understand and remember the material you are reading.
- *Summary:* Each chapter closes with a final section that in a bulleted list summarizes its key elements and provides you with an abstract of the covered material.
- *References:* The reference list accompanying each chapter can be considered more than just a list of the literature cited in the chapter. These citations

include review articles, reports of study findings, research discoveries, and other key references that can help you find additional information. We have tried to keep the majority of the references within 5 years of the book's publication so they are recent and relevant, although classic research is often still relevant and included.

- *Interdisciplinary boxes:* New to this edition, chapters include special boxes that summarize the role of specific disciplines relevant to the chapter's content. This feature emphasizes the interprofessional nature of caring for children with developmental disabilities.
- *Evidence-based practice boxes:* This new feature acknowledges the importance of evidence-based practice by summarizing the results of current research relevant to the topic and providing a "take-away message" so readers can apply the information to practice.
- *Appendices:* In addition to the Glossary, there are two other helpful appendices: 1) Syndromes and Inborn Errors of Metabolism, a mini-reference of pertinent information on inherited disorders causing developmental disabilities, and 2) Commonly Used Medications, to describe indications and side effects of medications often prescribed for children with disabilities.
- *Web site:* We have created a web site specific for *Children with Disabilities* that has additional content, including the following: 1) a resource directory of a wide range of national organizations, federal agencies, information sources, self-advocacy and accessibility programs, and support groups that can provide assistance to families and professionals; 2) a bank of 250 test questions for instructors; and 3) study questions and extension activities for every chapter. This content will be continuously updated.

CONTENT

In developing this eighth edition, we have aimed for a balance between consistency with the text that many of you have come to know so well and appreciate in its previous editions and innovation in exploring the new topics that demand our attention. All chapters have been substantially revised, and many have been rewritten to include an expanded focus on the psychosocial, rehabilitative, and educational interventions, as well as to provide information discovered

through educational, medical, and scientific advances since 2013.

Seven new chapters have been added, including the following.

- Chapter 7: The Senses: The World We See, Hear, and Feel
- Chapter 11: Child Development
- Chapter 28: Sleep Disorders
- Chapter 30: Interdisciplinary Education and Practice
- Chapter 38: Pharmacological Therapy
- Chapter 42: Racial and Ethnic Disparities

The new chapters focus on recently gained knowledge that is transforming our understanding of the causes and treatment of developmental disabilities.

The chapters are grouped into seven parts and organized to help guide readers through the breadth of content. Each part is detailed next.

Part I: The book starts with a section titled *As Life Begins*, which addresses what happens before, during, and/or shortly after birth to cause a child to be at increased risk for a developmental disability. The concepts and consequences of genetics, environmental influences, prenatal diagnosis, newborn screening, neonatal complication, and prematurity are explained.

Part II: The next section of the book, *The Child's Body: Physiology*, covers embryonic and fetal development, the sensory systems, the brain and central nervous system, muscles, bones and nerves, and the gastrointestinal tract—how they develop and work, and what can go wrong.

Part III: The third section covers *Developmental Assessment*. It includes chapters on typical and atypical development, diagnosing developmental disabilities, assessing physical disabilities, and neurocognitive and behavioral assessment.

Part IV: As its title implies, the fourth section, *Developmental Disabilities*, provides comprehensive descriptions of the major developmental disabilities and genetic syndromes that cause disabilities. This section includes chapters on intellectual disability, Down syndrome and fragile x syndrome, inborn errors of metabolism, speech and language disorders, autism spectrum disorder, attention-deficit/hyperactivity disorder, specific learning disabilities, cerebral palsy, epilepsy, acquired brain injury, and chronic diseases with related developmental disabilities.

Part V: The fifth section addresses *Associated Disabilities*, those disorders that occur more commonly in individuals with developmental disabilities. Chapters

include discussions on visual deficits, hearing impairment, behavioral/mental health issues, sleep disorders and feeding disorders.

Part VI: The sixth section focuses on Interventions. It contains chapters on interdisciplinary care, early intervention and special education services, (re)habilitative services, oral health care, behavioral therapy, assistive technology, family assistance, medication, and complementary health approaches.

Part VII: The final section is directed at Outcomes. This section concentrates on transition to adulthood, the effect of health care systems on outcomes, and health care disparities and their effect on outcomes in children with developmental disabilities.

THE CONTRIBUTORS AND REVIEW PROCESS

For contributors to this edition, we chose educators, physicians, dentists, psychologists, social workers, genetic counselors, occupational and physical therapists, speech-language pathologists, and other health care professionals who are experts in the areas they write about. Many are colleagues from Children's National Medical Center in Washington, D.C. Each chapter in the book has undergone editing at Paul H. Brookes Publishing Co. to ensure consistency in style and accessibility of content. Once the initial drafts were completed, each chapter was sent for peer review by major clinical and academic leaders in the field and was revised according to their input.

A FEW NOTES ABOUT TERMINOLOGY AND STYLE

As is the case with any book of this scope, the editors and contributors make decisions about the use of

particular words and the presentation style of information. We would like to share with you some of the decisions we have made for this book.

- *Categories of intellectual disability:* This book uses the American Psychiatric Association's categories according to the term *intellectual disability* (i.e., mild, moderate, severe, profound) when discussing medical diagnosis and treatment, and uses the categories that the American Association on Intellectual and Developmental Disabilities (formerly the American Association on Mental Retardation) established in 1992 (i.e., requiring limited, intermittent, extensive, or pervasive support) when discussing educational and other interventions, thus emphasizing the capabilities rather than the impairments of individuals with intellectual disability.
- *"Typical" versus "normal":* Recognizing diversity and the fact that no one type of person or lifestyle is inherently "normal," we have chosen to refer to the general population of children as "typical" or "typically developing," meaning that they follow the natural continuum of development.
- *Person-first language:* We have tried to preserve the dignity and personhood of all individuals with disabilities by consistently using person-first language, speaking, for example, of "a child with cerebral palsy," instead of "a cerebral palsied child." In this way, we are able to emphasize the person, not define him or her by the condition.

As you read this eighth edition of *Children with Disabilities*, we hope you will find that the text continues to address the frequently asked question, "Why this child?" and to provide the medical background you need to care for children with developmental disabilities.

Acknowledgments

We would like to thank our colleagues at Paul H. Brookes Publishing Co., Inc., for their great help. Jolynn Gower served as Acquisitions Editor, Liz Gildea as Associate Editor, and Stephanie Henderson as Editorial Assistant, providing developmental oversight and management of the project. Nicole Schmidl managed the production of the book, and Janet Wehner managed the production of the online content. We also would like to acknowledge Nancy Peterson, who helped organize this project as well as contributed to its editorial development.

A book such as *Children with Disabilities* is best understood with illustrations that help to explain medical concepts. Expert medical illustrators are crucial in this effort. Elaine Kasmer and Lynn Reynolds have contributed to this endeavor in previous editions, and Catherine Twomey has created new illustrations for this eighth edition. We deeply acknowledge their important contributions.

We thank previous contributors whose work on the seventh edition laid an excellent foundation for this text: Kruti Acharya, George Acs, Stephen Baumgart, Donna Bernhardt Bainbridge, Michelle L. Bestic, Michael J. Bina, Pamela Buethe, Philippa Campbell, Marilyn Cataldo, Michael F. Cataldo, Taeun Chang, Iser G. DeLeon, Nienke P. Dosa, Patrick C. Friman, Chrysanthe Gaitatzes, Brooke E. Geddie, Arlene Gendron, James Gleason, Rebecca M. Haesler, Gilbert R. Herer, Susan L. Hyman, SungWoo Kahng, Robert Keating, Brendan Lanpher, Susan E. Levy, Michelle Huckaby Lewis, Marijean M. Miller, Jocelyn J. Mills, Jerome Paulson, Steven P. Perlman, Adré J. du Plessis, Vincent Schuyler, Peter J. Smith, Sheela Stuart, Adrienne S. Tedeschi, Frances Tolley, Betty R. Vohr, Patience H. White, Amanda Yaun, and Michelle H. Zimmer. Finally, many of our colleagues reviewed and edited the manuscript for content and accuracy, and we would like to acknowledge their efforts.

Why me?
Why me?
Why do I have to do so much more than others?
Why am I so forgetful?
Why am I so hyperactive?
And why can't I spell?
Why me? O'why me?

I remember when I almost failed first grade because I couldn't read. I would cry hour after hour because my mother would try to make me read. Now I love to read. I couldn't write in cursive but my mother helped me and now I can. I don't have as bad a learning disability as others. At least I can go to a normal school. I am trying as hard as I can (I just hope it is enough). My worst nightmare is to go to a special school because I don't want to be treated differently.

I am getting to like working. I guess since my dad is so successful and has a learning disability, it helps make me not want to give up. Many people say that I am smart, but sometimes I doubt it. I am very good at math, but sometimes I read a number like 169 as 196, so that messes things up. I also hear things incorrectly, for instance entrepreneur as horse manure (that really happened). I guess the reason why a lot of people don't like me is because I say the wrong answer a lot of times.

I had to take medication, but then I got off the medication and did well. Then in 7th grade I wasn't doing well but I didn't tell my parents because I thought they would just scream at me. My dad talked to the guidance counselor and found out. It wasn't till a week ago that I started on the medication again; I have been doing fine since then. As I have been getting more organized, I have had more free time. I guess I feel good when I succeed in things that take hard work.

This is my true story . . .

Andrew Batshaw

Andrew Batshaw
1989 (age 12)

Twenty-eight years ago, I wrote the first letter that appears in this book. I was 12, a child on the cusp of becoming a teenager, and grappling (emotionally, socially, and intellectually) with my learning disability. I felt like its victim. I was scared and ashamed. I was unsure if I'd have the opportunities that others had, and even worse, unsure if I'd be able to live what I imagined was a normal life. Fortunately for me, I was born with not just a learning disability but also many advantages. I am naturally hopeful, curious, and smart, and I was born into a loving family with the means and knowledge to support me.

I am now 40 years old and living a life that my 12-year-old self would have found extraordinary. I am enjoying a time of stability, growth, and powerful impact. My wife and I are thrilled to be celebrating our 13th wedding anniversary this year. Our children, Gia and Mika, are now older and more independent at 10 and 8; they are healthy, bright, and beautiful. I have satisfying relationships including long-term friendships with people I met around the time I wrote that first letter. On the work front, I have found my home: I am proud to serve as the CTO and a co-founder of Waggl, a 60-person company that provides an innovative real-time feedback platform for employees. I am so proud to have built an organization where employees love to work and where we improve the work lives of hundreds of thousands of people every year. In my role, I get to lead not just the technology of the company but also its culture and how we grow as an organization.

Right now, my eldest daughter Gia is nearing the age that I was when I wrote my first letter, and I am nearing the age that my father was. Over the last several years, my daughters have been learning to read, write, and spell. I have found myself occasionally feeling anxious that they might also have learning disabilities and that they, too, would struggle as I did through much of their childhood. When I sat down to read with them in the early days, it often brought back painful memories. Sometimes when they were frustrated sounding out an unknown word, it was as if I were back at the living room table with my mother, looking at a word, trying as hard as I could to figure it out, and failing. When my youngest, Mika, came home one day and said without concern, "I think I am in the easiest spelling group," I immediately thought of being sorted into reading groups in second grade and wondering why I was in the group with the kids who were always struggling in class. When she has trouble sitting still and focusing on what we are discussing, I can't help but wonder, "Does she have ADHD, or is that normal behavior for a second-grader?" Both of their teachers have reassured us that they are doing well, and are learning and focused in class. So, I am happy to say that there aren't any real indications that either daughter inherited my disability. Even so, I sometimes think, what if they did?

I've imagined that Andrew from 1989 was my child. What would I do for him now? I don't think I could replicate what my mom did for me—devoting herself with heroic patience, time, and energy to support me academically—but I could arrange for daily support. I would enroll him in a regular private school to allow him more individualized attention than public school could offer (but respect his wishes not to go to a specialized school). Like my father, I would share my childhood struggles with Andrew. I would share the letters I have written over the years about my disability to help him understand the kind of journey that is ahead of him and how much better things get. I would give him tools for working with his feelings of frustration and inadequacy, and I would teach him to meditate. I would encourage him to pursue nonacademic interests to give him a variety of experiences of success.

And . . . I would sit him down and read his letter “Why Me?” . . . look him straight in the eye and say, “I know this is hard right now, and that you are struggling. You may not believe this, but this struggle will serve you. You are worried that you may not be able to live a normal life. This struggle will help you live an **extraordinary** life. Why you? Because someday you will transcend this disability. In that process, you will learn things that will make you successful . . . and, even more importantly, will help you make this world a better place.”

A handwritten signature in black ink, appearing to read "Andrew Batshaw". The signature is fluid and cursive, with a long horizontal stroke extending from the end.

*Dedicated to all of the families we have been honored to serve
and to the health care professionals we have taught
so they could expertly care for children with disabilities*

PART I

As Life Begins

CHAPTER 1

The Genetics Underlying Developmental Disabilities

Mark L. Batshaw, Eyby Leon,
and Monisha S. Kisling

Upon completion of this chapter, the reader will

- Know about the human genome and its implication for the origins of developmental disabilities
- Be able to explain how errors in cell division can cause genetic syndromes
- Know about Mendelian inheritance
- Recognize the importance of mutations and genetic variation
- Understand the ways that genes can be affected by the environment in which they reside, i.e., epigenetics
- Know about genetic testing for the origins of developmental disability
- Be aware of novel genetic treatment approaches

Whether we have brown or blue eyes is determined by genes passed on to us from our parents. Other traits, such as height and weight, are affected by genes and by our environment both before and after birth. In a similar manner, genes alone or in combination with environmental factors can place children at increased risk for many developmental disorders, including birth defects such as meningomyelocele (spina bifida). In the case of meningomyelocele, a maternal nutritional deficiency of folic acid can markedly increase the risk of the genetic disorder. Disorders associated with developmental disabilities have a spectrum of genetic and environmental origins. Some disorders are purely genetic, such as Tay-Sachs disease (a progressive neurologic disorder) and result from a defect in a **single gene**, while others like Down syndrome (see Chapter 15), result from a chromosomal error, in which an

extra chromosome containing hundreds of genes exists. Other developmental disorders result from purely environmental exposures, including prenatal viral infections such as cytomegalovirus and teratogenic agents like alcohol and thalidomide (see Chapter 2). There are also conditions in which genes are affected by their environment, leading to epigenetic disorders such as fragile X syndrome and Angelman syndrome.

As an introduction to the topics discussed in the other chapters of this volume, this chapter describes the human cell and explains chromosomes and genes. It also reviews and provides illustrations and examples of the errors that can occur in the processes of **meiosis** (reductive cell division) and **mitosis** (cell replication), summarizes inheritance patterns of single-gene disorders, and presents the concept of epigenetics. Furthermore, this chapter discusses innovative treatments

that manipulate or use an understanding of the child's genome to improve an outcome. It is important to understand that while these disorders are individually rare, genetic alterations underlie almost half of developmental disabilities. Medical treatment is increasingly available for a number of these disorders, though often at great cost.

■ ■ ■ CASE STUDY

Katy developed typically until she was 2 years old, when she started to have episodes of vomiting and lethargy after high-protein meals. Her parents became very concerned because their older son, Andrew, had died in infancy after an episode of lethargy and seizures was followed by coma, although no specific diagnosis had been made. After extensive testing by a genetic specialist, Katy was discovered to have a specific mutation or error in the gene that codes for ornithine transcarbamylase (OTC), an enzyme that prevents the accumulation of toxic ammonia in the body and brain. The OTC gene is located on the X chromosome; since girls have two X chromosomes, when one X has the mutation, there is a second normal copy to mitigate the defect. As a result, girls are less likely to be affected by X-linked disorders than boys, and, when affected, they generally have less severe symptoms. After Katy was diagnosed with OTC deficiency, her specialist tested DNA that was extracted before Andrew's death and found that he too carried this mutation. Katy was placed on a low-protein diet and given a medicine to provide an alternate pathway to rid the body of ammonia, and she has done well. Now age 7, she appears to have a mild nonverbal learning disability resulting from her prior metabolic crises; if Katy had been left untreated, she would probably not be alive.

Thought Questions:

How often do we miss a genetic diagnosis as a cause of developmental disabilities? Could earlier diagnosis and treatment improve outcomes in many of these cases?

GENETIC DISORDERS

The human body is composed of approximately 100 trillion cells. There are many cell types: nerve cells, muscle cells, white blood cells, liver cells and skin cells, to name a few. All cells, with the exception of the red blood cell, are divided into two compartments: a central, enclosed core—the **nucleus**—and an outer area—the **cytoplasm** (Figure 1.1). The red blood cell differs insofar as it does not have a nucleus. The nucleus houses **chromosomes**, structures that contain the genetic code—DNA (**deoxy-ribonucleic acid**), which is organized into hundreds of

Figure 1.1. An idealized cell. The genes within chromosomes direct the creation of a product on the ribosomes. The product is then packaged in the Golgi apparatus and released from the cell.

genes (units of heredity) in each chromosome. There are 23 pairs of chromosomes and about 20,000 protein-coding genes that collectively make up the human **genome**. These genes are responsible for our physical attributes and for the biological functioning of our bodies. Under the direction of the genes, the products that are needed for the organism's development and functions, such as waste disposal and the release of energy, are made in the cytoplasm. The nucleus contains the blueprint for the organism's growth and development, and the cytoplasm manufactures the products needed to complete the task.

When there is a defect within this system, the result may be a genetic disorder, often causing developmental disabilities. These disorders take many forms. They include the addition of an entire chromosome in each cell (e.g., Down syndrome), the loss of an entire chromosome in each cell (e.g., Turner syndrome), and the loss or deletion of a significant portion of a chromosome (e.g., Cri-du-chat syndrome). There can also be a **microdeletion** of a number of closely spaced or contiguous genes within a chromosome (e.g., chromosome 22q11.2 deletion syndrome, also called velocardiofacial syndrome [VCFS]). Microdeletions may have varied expression depending on stochastic (randomly determined) and environmental processes, as well as on genetic effects, with these factors potentially acting alone or in combination (Bertini et al., 2017). Finally, there can be a defect within a single gene (e.g., phenylketonuria) or altered expression of the gene (e.g., Rett syndrome). This chapter discusses each of these types of genetic defects.

CHROMOSOMES

Each organism has a fixed number of chromosomes that directs the cell's activities. In each human cell,

there are normally 46 chromosomes. Each chromosome contains many genes, but some chromosomes have more (e.g., 500–800 gene loci in chromosomes 1, 19, and X) and others have fewer (50–120 in chromosomes 13, 18, 21, and Y). The 46 chromosomes are organized into 23 pairs. Typically, one chromosome in each pair comes from the mother and the other from the father. Egg and sperm cells, unlike all other human cells, each contains only 23 chromosomes. During conception, these **germ cells** (i.e., sperm and eggs) fuse to produce a fertilized egg with the full complement of 46 chromosomes.

Among the 23 pairs of chromosomes, 22 are termed **autosomes**. The 23rd pair consists of the X and Y chromosomes and are called the **sex chromosomes**. The Y chromosome, which is involved in male sex determination and development, is one-third to one-half the size of the X chromosome, has a different shape, and has far fewer genes. Two X chromosomes determine the child to be female; an X and a Y chromosome determine the child to be male.

CELL DIVISION AND ITS DISORDERS

Cells have the ability to divide into daughter cells that contain genetic information that is identical to the information from the parent cell. The prenatal development of a human being is accomplished through cell division, differentiation into different cell types, and movement of cells to different locations in the body. There are two kinds of cell division: **mitosis** and **meiosis**. In mitosis, or nonreductive division, 2 daughter cells, each containing 46 chromosomes, are formed from 1 parent cell. In meiosis, or reductive division, 4 daughter cells, each containing only 23 chromosomes, are formed from 1 parent cell. Although mitosis occurs in all cells, meiosis takes place only in the germ cells.

The ability of cells to continue to undergo mitosis throughout the life span is essential for proper bodily functioning. Cells divide at different rates, however, ranging from once every 10 hours for skin cells to once a year for liver cells. This is why a skin abrasion heals in a few days but the liver may take a year to recover from hepatitis. By adulthood, some cells, including neurons and muscle cells, appear to have a significantly decreased ability to divide. This limits the body's capacity to recover after medical events, such as strokes, or from traumatic injuries.

One of the primary differences between mitosis and meiosis can be seen during the first of the two meiotic divisions. During this cell division, the corresponding chromosomes line up beside each other in pairs (e.g., both copies of chromosome 1 line up together). Unlike in mitosis, however, they intertwine

and may “cross over,” exchanging genetic material. This adds variability. Although this crossing over (or recombination) of the chromosomes may result in disorders (e.g., deletions), it also allows for the mutual transfer of genetic information, reducing the chance that siblings end up as exact copies (clones) of each other. Some of the variability among siblings can also be attributed to the random assortment of maternal and paternal chromosomes during the first of the two meiotic divisions.

Throughout the life span of the male, meiosis of the immature sperm produces **spermatocytes** with 23 chromosomes each. These cells will lose most of their cytoplasm, sprout tails, and become mature sperm. This process is termed spermatogenesis. In the female, meiosis forms oocytes that will ultimately become mature eggs in a process called oogenesis. By the time a girl is born, her body has produced all of the approximately 2 million eggs she will ever have.

A number of events that adversely affect a child's development can occur during meiosis. When chromosomes divide unequally, a process known as **nondisjunction** occurs; as a result, 1 daughter egg or sperm contains 24 chromosomes and the other 22 chromosomes. Meiotic nondisjunction, particularly in oogenesis, is the most common mutational mechanism in humans responsible for chromosomally atypical fetuses. Usually, these cells do not survive, but occasionally they do and can lead to the child being born with too many chromosomes (e.g., Down syndrome) or too few (e.g., Turner syndrome). Notably, the most commonly found **trisomy** in miscarriages is trisomy 16, and embryos with trisomy 16 are never carried to term (Nussbaum, McInnes, & Willard, 2016). The chromosome 16 contains so many genes important for normal development that its disruption is incompatible with life. Conversely, trisomies 13, 18, and 21 are the most commonly observed full trisomies at birth (Mai et al., 2013). However, even in these conditions, the vast majority of embryos with the defect do not survive.

The majority of fetuses carrying chromosomal abnormalities are spontaneously aborted. Among those children who survive these genetic missteps, **intellectual disability**, unusual (dysmorphic) facial appearances, and various congenital organ malformations are common. In the general population, chromosomal errors causing disorders occur in 6–9 per 1,000 of all live births. In children who have intellectual disability, however, the prevalence of chromosomal abnormality increases, being responsible for 20% of the cases (Martin & Ledbetter, 2017). It is also clear that as the woman ages, the risk of errors in meiosis increases, as is typified by Down syndrome.

Chromosomal Gain: Down Syndrome

The most frequent chromosomal abnormality is unequal division of non-sex chromosomes, and the most common clinical consequence is trisomy 21, or Down syndrome (Nussbaum, McInnes, & Willard, 2016; also see Chapter 15). Nondisjunction can occur during either mitosis or meiosis but is more common in meiosis (Figure 1.2). When nondisjunction occurs during the first meiotic division, both copies of chromosome 21 end up in one cell. Instead of an equal distribution of chromosomes among cells (23 each), 1 daughter cell receives 24 chromosomes and the other receives only 22. The cell containing 22 chromosomes is unable to survive. However, the egg (or sperm) with 24 chromosomes occasionally can survive. After fertilization with a sperm (or egg) containing 23 chromosomes, the resulting embryo contains 3 copies of chromosome 21, or trisomy 21. The child will be born with 47 rather than 46 chromosomes in each cell and will thus have Down syndrome (Figure 1.3).

The majority of individuals with Down syndrome (approximately 95%) have trisomy 21. This trisomy results from nondisjunction during meiosis in oogenesis in 90% of the cases and from nondisjunction during spermatogenesis in 10% (Nussbaum, McInnes, & Willard, 2016). This disparity is partially due to the increased rate of autosomal nondisjunction in egg production, but also to the lack of viability of sperm with an extra chromosome 21. Another 3%–4% of individuals

Figure 1.3. Karyotype of a boy with Down syndrome (47, XY). Note that the child has 47 chromosomes; the extra one is a chromosome 21.

acquire Down syndrome as a result of **translocation** (discussed later) and 1%–2% acquire it from **mosaicism** (some cells being affected and others not; this is also discussed later).

Chromosomal Loss: Turner Syndrome

Turner syndrome is the only disorder in which a fetus can survive despite the loss of an entire chromosome. Even so, more than 99% of the 45,X conceptions appear

Figure 1.2. Nondisjunction of chromosome 21 in meiosis. Unequal division during meiosis I or meiosis II can result in trisomy or monosomy.

to be miscarried (Hook & Warburton, 2014). Females with Turner syndrome (1 in every 5,000 live births) have a single X chromosome and no second X or Y chromosome, for a total of 45, rather than 46, chromosomes. In contrast to Down syndrome, 80% of individuals with **monosomy** X conditions are affected by meiotic errors in sperm production; these children usually receive an X chromosome from their mothers but no sex chromosome from their fathers.

Girls with Turner syndrome typically have short stature, a webbed neck, a broad “shield-like” chest with widely spaced nipples, and nonfunctional ovaries. Twenty percent have obstruction of the left side of the heart, most commonly caused by a **coarctation** of the **aorta**. Unlike children with Down syndrome, most girls with Turner syndrome develop typically. They do, however, have visual-perceptual impairments that predispose them to develop nonverbal learning disabilities (Table 1.1; Hong & Reiss, 2014). Human growth hormone injections have been effective in increasing height in girls with Turner syndrome, and **estrogen** supplementation can lead to the emergence of secondary sexual characteristics; however, these girls remain infertile.

Mosaicism

In mosaicism, cells in the same individual have different genetic makeups (Nussbaum, McInnes, & Willard, 2016). For example, a child with the mosaic form of Down syndrome may have trisomy 21 in skin cells but not in blood cells. or the individual may have trisomy 21 in some, but not all, brain cells. Children with mosaicism often appear as though they have a particular condition (in this example, Down syndrome); however, the physical/organ and cognitive impairments may be less severe. Usually mosaicism occurs when some cells in a trisomy conception lose the extra chromosome via non-disjunction during mitosis. Mosaicism also can occur if some cells lose a chromosome after a normal conception (e.g., some cells lose an X chromosome in mosaic Turner syndrome). Mosaicism is present in only 5%–10% of all children with chromosomal abnormalities.

Translocations

A relatively common dysfunction in cell division, translocation can occur during mitosis and meiosis when the chromosomes break and then exchange parts with other chromosomes. Translocation involves the transfer of a portion of one chromosome to a completely different chromosome. For example, a portion of chromosome 21 might attach itself to chromosome 14 (Figure 1.4). If this occurs during meiosis, 1 daughter cell will then have 23 chromosomes but will have both a chromosome 21 and a chromosome 14/21 translocation. Fertilization of this egg, by a sperm with a cell containing the normal complement of 23 chromosomes, will result in a child with 46 chromosomes. This includes two copies of chromosome 21, one chromosome 14/21, and one chromosome 14. This child will have Down syndrome because of the functional trisomy 21 caused by the translocation.

Deletions

Another somewhat common dysfunction in cell division is deletion. Here, part, but not all, of a chromosome is lost. Chromosomal deletions occur in two forms: visible deletions and microdeletions. Those that are large enough to be seen through the microscope are called visible deletions. Those that are so small that they can only be detected at the molecular level are called microdeletions and can be identified by a test called chromosomal microarray.

Figure 1.4. Translocation. During **prophase** of meiosis in a parent, there may be a transfer of a portion of one chromosome to another. In this figure, the long arm of chromosome 21 is translocated to chromosome 14, and the residual fragments are lost.

Table 1.1. Neurocognitive deficits in Turner syndrome

Intellectual function	Typical but 5–10 points below siblings; verbal IQ > performance IQ
Visual spatial	Deficits in spatial orientation
Math	Difficulties with calculation
Executive function	Impairment in attention, processing speed, working memory, cognitive flexibility, and planning
Social	Impairments in face recognition and social reciprocity
Behavior	Overall risk of attention-deficit/hyperactivity disorder and dyscalculia; equivocal evidence for autism

Source: Hong and Reiss (2014).

Cri-du-chat (“cat cry”) syndrome is an example of a visible chromosomal deletion in which a portion of the short arm of chromosome 5 is lost. Cri-du-chat syndrome affects approximately 1 in 50,000 children, causing microcephaly and an unusual facial appearance with a round face, widely spaced eyes, **epicanthal folds**, and low-set ears. Children with the syndrome have a high-pitched cry and intellectual disability (Cerruti Mainardi, 2006).

Examples of **microdeletion syndromes** (also called **contiguous gene syndromes** because they involve the deletion of a number of adjacent genes) include Smith-Magenis syndrome, Williams syndrome, and VCFS (Weischenfeldt, Symmons, Spitz, & Korb, 2013). Smith-Magenis is caused by a microdeletion in the short arm of chromosome 17, Williams syndrome by a deletion in the long arm of chromosome 7, and VCFS by a deletion in the long arm of chromosome 22. Children with Smith-Magenis syndrome have feeding difficulties, hypotonia, distinctive facial features, self-injurious behavior, and intellectual disability. Children with Williams syndrome likewise have intellectual disability with a distinctive facial appearance, but they also have cardiac defects and a unique cognitive profile with apparent expressive language skills beyond what would be expected based on their cognitive abilities. Children with VCFS syndrome may have a cleft palate, a congenital heart defect, a characteristic facial appearance, and/or a nonverbal learning disability. Cognitive problems are often present, and many affected children satisfy the criteria for a diagnosis of autism.

Frequency of Chromosomal Abnormalities

In total, approximately 25% of eggs and 3%–4% of sperm have an extra or missing chromosome, and an additional 1% and 5%, respectively, have a structural chromosomal abnormality (Hassold, Hall, & Hunt, 2007). As a result, 10%–15% of all conceptions have a chromosomal abnormality. Somewhat more than 50% of these abnormalities are trisomies, 20% are monosomies, and 15% are **triploidies** (69 chromosomes). The remaining chromosomal abnormalities are composed of structural abnormalities and **tetraploidies** (92 chromosomes). It may therefore seem surprising that more children are not born with chromosomal abnormalities. The explanation is that more than 95% of fetuses with chromosomal abnormalities do not survive to term. In fact, many are lost very early in gestation, even before a pregnancy may be recognized.

GENES AND THEIR DISORDERS

The underlying problem with the previously mentioned chromosomal disorders is the presence of too many or

too few genes resulting from extra or missing chromosomal material. Genetic disorders can also result from an abnormality in a single gene. As noted above, there are about 20,000 genes in the human genome. This is quite remarkable given that the fruit fly has approximately 13,000 genes, the round worm 19,000 genes, and a simple plant 26,000 genes. It was previously thought that each gene regulated the production of a single protein. Now it is known that the situation is much more complex; single genes in humans code for multiple proteins, giving humans the combinational diversity that lower organisms lack. Humans can produce approximately 100,000 proteins from less than one-quarter of that many genes. However, it must be acknowledged that the chimp shares 99% of the human genome. Having now examined the genome of innumerable organisms, the minimum number of genes necessary for life appears to be approximately 300; all living organisms share these same 300 genes.

The mechanism by which genes act as blueprints for producing specific proteins needed for body functions is as follows. Genes are composed of various lengths of DNA that, together with intervening DNA sequences, form chromosomes. DNA is formed as a **double helix**, a structure that resembles a twisted ladder (Figure 1.5). The sides of the ladder are composed of sugar and phosphate molecules, whereas the “rungs” are made up of four chemicals called **nucleotide bases**: **cytosine** (C), **guanine** (G), **adenine** (A), and **thymine** (T). Pairs of nucleotide bases interlock to form each rung: cytosine bonds with guanine, and adenine bonds with thymine. The sequence of nucleotide bases on a segment of DNA (spelled out by the four-letter alphabet C, G, A, T) make up an individual’s genetic code. Individual genes range in size, containing from 1,500 to more than 2 million nucleotide–base pairs. Overall, there are approximately 3.3 billion base pairs in the human genome, but only about 1% encode genes that serve as a blueprint for protein production. It should also be noted that all genes are not “turned on” or expressed at all times. Some are only active during fetal

Figure 1.5. Deoxyribonucleic acid (DNA). Four nucleotides (C, cytosine; G, guanine; A, adenine; T, thymine) form the genetic code. On the mRNA molecule, uracil (U) substitutes for thymine. The DNA unzips to transcribe its message as mRNA.

life (e.g., the fetal hemoglobin gene), and it is hoped that some are never expressed (e.g., oncogenes, which have the potential to cause cancer). The turning on and off of genes usually follows a carefully developmentally regulated process, but it can also be influenced by the environment. Regulation of gene expression plays a particularly important role during fetal development; as a result, problems involving gene expression during fetal development can be particularly devastating. The way gene expression is regulated involves a number of structural changes to the DNA and its architecture without altering the actual nucleotide sequence of the DNA. This process is termed *epigenetics* and is a cause of a number of genetic syndromes that are associated with developmental disabilities.

Transcription

The production of a specific protein begins when the DNA comprising that gene unwinds and the two strands (the sides of the ladder) unzip to expose the genetic code (Jorde, Carey, & Bamshad, 2015). The exposed DNA sequence then serves as a template for the formation, or **transcription** (the writing out), of a similar nucleotide sequence called **messenger ribonucleic acid** (mRNA; Figure 1.6). In all RNA, the nucleotides are the same as in DNA except that uracil (U) substitutes for thymine (T). In most genes, coding regions (**exons**) are interrupted by noncoding regions (**introns**). During transcription, the entire gene is copied into a pre-mRNA, which includes exons and introns. During the process of RNA splicing, introns are removed and exons are joined to form a contiguous coding sequence. In its entirety, the part of the human genome formed by

Figure 1.6. A summary of the steps leading from gene to protein formation. Transcription of the DNA (gene) onto mRNA occurs in the cell nucleus. The mRNA is then transported to the cytoplasm, where translation into protein occurs.

exons is called the **exome**. As might be expected, errors or mutations may occur during transcription; however, a proofreading enzyme generally catches and repairs these errors. If not corrected, however, transcription errors can lead to the production of a disordered protein and a disease state.

Translation

Once transcribed, the single-stranded mRNA detaches and the double-stranded DNA zips back together. The mRNA then moves out of the nucleus into the cytoplasm, where it provides instructions for the production of a protein, a process termed **translation** (Figure 1.7). The mRNA attaches itself to a **ribosome**. The ribosome moves along the mRNA strand, reading the message in three-letter “words,” or **codons**, such as GCU, CUA, and UAG. Most of these triplets code for specific **amino acids**, the building blocks of proteins. As these triplets are read, another type of RNA, transfer RNA (tRNA), carries the requisite amino acids to the ribosome, where they are linked to form a protein.

Figure 1.7. Translation of mRNA into protein. The ribosome moves along the mRNA strand assembling a growing polypeptide chain using tRNA–amino acid complexes. In this example, it has already assembled six amino acids (phenylalanine [Phe], arginine [Arg], histidine [His], cystine [Cys], threonine [Thr], and glycine [Gly]) into a polypeptide chain that will become a protein.

Certain triplets, termed *stop codons*, instruct the ribosome to terminate the sequence by indicating that all of the correct amino acids are in place to form the complete protein, for example, thyroid hormone.

Once the protein is complete, the mRNA, ribosome, and protein separate. The protein is released into the cytoplasm and is either used by the cytoplasm or prepared for secretion into the bloodstream. If the protein is to be secreted, it is transferred to the **Golgi apparatus** (Figure 1.1), which packages it in a form that can be released through the cell membrane and carried throughout the body.

Mutations

An abnormality at any step in the transcription or translation process can cause the body to produce a structurally abnormal protein, reduced amounts of a protein, or no protein at all. When the error occurs in the gene itself, thus disrupting the subsequent steps, that mistake is termed a *mutation*. The likelihood of mutations occurring increases with the size of the gene. In sperm cells, the point mutation rate also increases with paternal age. Although most mutations occur spontaneously, they can be induced by radiation, toxins, and viruses. Once they occur, mutations become part of a person's genetic code. If they are present in the germline, they can be passed on from one generation to the next.

Point Mutations The most common type of mutation is a single base pair substitution (Jorde et al., 2015), also called a **point mutation**. Because there is redundancy in human DNA, many point mutations have no adverse consequences. Depending on where in the gene they occur, however, point mutations are capable of

causing a **missense mutation** or a **nonsense mutation** (Figure 1.8). A missense mutation results in a change in the triplet code that substitutes a different amino acid in the protein chain. For example, in most cases of the inborn error of metabolism, **phenylketonuria** (PKU), a single base substitution causes an error in the production of phenylalanine hydroxylase, the enzyme necessary to metabolize the amino acid **phenylalanine**. The result is an accumulation of phenylalanine that can cause brain damage (see Chapter 16). In a nonsense mutation, the single base pair substitution produces a stop codon that prematurely terminates the protein formation. In this case, no useful protein is formed. **Neurofibromatosis-1** (NF1) is an example of a disorder commonly caused by a nonsense mutation. In NF1 a tumor suppressor, neurofibromin, is not formed. As a result, multiple benign neurofibroma tumors form on the body and in the brain. Children with NF1 also have a high incidence of attention-deficit/hyperactivity disorder (Friedman, 2014).

Insertions and Deletions Mutations can also involve the insertion or deletion of one or more nucleotide bases. As one example, insertion of nucleotides in the fukutin gene (expressed in muscle, brain, and eyes) can affect its function when associated with other mutations and cause Fukuyama congenital muscular dystrophy (Saito, 2012). In contrast, a common mutation in another inherited muscle disease, Duchenne muscular dystrophy, usually involves a deletion in the dystrophin gene (see Chapter 9).

Base additions or subtractions may also lead to a **frame shift** in which the three-base-pair reading frame is shifted. All subsequent triplets are misread, often leading to the production of a stop codon and a non-functional protein. Certain children with Tay-Sachs disease have this type of mutation. Other mutations

	Missense Mutation				Nonsense Mutation				Frame shift Mutation			
DNA	AAG	AGT	GTA	CGT	AAG	AGT	GTA	CGT	AAG	AGT	GTA	CGT
mRNA	TTC	TCA	CAT	GCA	TTC	TCA	CAT	GCA	TTC	TCA	CAT	GCA

Figure 1.8. Examples of point mutations: Missense mutation, nonsense mutation, and frame shift mutation. The shaded areas mark the point of mutation.

can affect regions of the gene that regulate transcription but that do not actually code for an amino acid. These areas are called promoter and enhancer areas. They help turn other genes on and off and are very important in the normal development of the fetus. A mutation in a transcription gene leads to **Rubinstein-Taybi syndrome**, which is associated with multiple congenital malformations and severe intellectual disability (Spena, Gervasini, & Milani, 2015). Mutations in a transcription gene also may result in a normal protein being formed but at a much slower rate than usual, leading to an enzyme or other protein deficiency. An example is **Cornelia de Lange syndrome**, in which patients have a mutation in the NIPBL gene that codes for the developmentally important cohesin-loading protein, delangin. Affected children manifest growth delay, a dysmorphic appearance including confluent eyebrows, limb impairments, and intellectual disability.

Selective Advantage

The **incidence** of a genetic disease in a population depends on the difference between the rate of mutation production and that of mutation removal. Typically, genetic diseases enter populations through mutation errors. Natural selection, the process by which individuals with a selective advantage survive and pass on their genes, works to remove these errors. For instance, because individuals with sickle cell disease (an **autosomal recessive** inherited blood disorder) historically have had a decreased life span, the gene that causes this disorder would have been expected to be removed from the gene pool over time. Sometimes natural selection, however, favors the individual who is a carrier of one copy of a mutated recessive gene. In the case of sickle cell disease, unaffected carriers (called heterozygotes) who appear clinically healthy actually have minor differences in their hemoglobin structure that make it more resistant to a malarial parasite (López, Saravia, Gomez, Hoebeke, & Patarroyo, 2010). In Africa, where malaria is endemic, carriers of this disorder have a selective advantage. This selective advantage has maintained the sickle cell trait among Africans. Northern Europeans, for whom malaria is not an issue, rarely carry the sickle cell gene at all; this mutation has presumably died out via natural selection in this population (Jorde et al., 2015).

Single Nucleotide Polymorphisms

Despite the more than 3 billion base pairs in the genetic code, people of all races and geography share a 99.9% genetic identity (Ridley, 2006). Although this is quite remarkable, that 0.1% difference means there are about

3 million DNA sequence variations, also called **single nucleotide polymorphisms** (SNPs). This genetic variation is the basis of evolution, but it can also contribute to health, unique traits, or disease. One SNP involved in muscle formation, if present, makes individuals much more likely to become “buff” if they weight lift; another SNP is associated with perfect musical pitch. There is an SNP that makes individuals more susceptible to adverse effects from certain medications because it leads to slower metabolism of drugs by the liver. There also are SNPs that place people at greater risk for developing Alzheimer’s disease and an inflammatory bowel disease called Crohn’s disease (Uniken Venema, Voskuil, Dijkstra, Weersma, & Festen, 2016). Knowledge of these SNPs, as well as candidate disease genes, allows a better understanding of certain genetic conditions, which can lead to the development of novel treatments.

Single-Gene (Mendelian) Disorders

Gregor Mendel (1822–1884), an Austrian monk, pioneered our understanding of single-gene defects. While cultivating pea plants, he noted that when he bred two differently colored plants—yellow and green—the **hybrid** offspring all were green rather than mixed in color. Mendel concluded that the green trait was **dominant**, whereas the yellow trait was **recessive** (from the Latin word for “hidden”). However, the yellow trait sometimes appeared in subsequent generations. Later, scientists determined that many human traits, including some birth defects, are also inherited in this fashion. They are referred to as **Mendelian traits**.

Table 1.2 indicates the prevalence of some common single-gene disorders associated with developmental disabilities. Approximately 1% of the population has a known single-gene disorder. These disorders can be transmitted to offspring on the autosomes or on the X chromosome. Mendelian traits may be either dominant or recessive. Thus, Mendelian disorders are characterized as being **autosomal recessive**, **autosomal dominant**, or **X-linked**.

Autosomal Recessive Disorders Among the currently recognized Mendelian disorders, over 1,000 are inherited as autosomal recessive traits (McKusick-Nathans Institute of Genetic Medicine & The National Center for Biotechnology Information, 2017). For a child to have a disorder that is autosomal recessive, he or she must carry an abnormal gene on both copies of the relevant chromosome. In the vast majority of cases, this means that the child receives an abnormal copy from both parents. The one exception is uniparental disomy, which is discussed in the next section.

Table 1.2. Prevalence of genetic disorders

Disease	Appropriate prevalence
Chromosomal disorders	
Down syndrome (trisomy 21)	1/850
Klinefelter syndrome (47, XXY)	1/600
Trisomy 13	1/12,000–1/20,000
Trisomy 18	1/6,000–8,000
Turner syndrome (45, X)	1/2,500–1/4,000 females
Single-gene disorders	
Duchenne muscular dystrophy	1/3,300 males
Fragile X syndrome	1/3,000–1/4,000 males; 1/8,000 females
Neurofibromatosis type I	1/3,000
Phenylketonuria	1/5,000 to 1/10,000
Tay-Sachs disease	1/3,600 Ashkenazi Jews
Mitochondrial inheritance	
Leber hereditary optic neuropathy	Rare 1/30,000–1/50,000
MERRF	Rare (< 1/100,000)
MELAS	Rare, unknown

Sources: Nussbaum, McInnes, and Willard (2016) and Adam, Ardinger, Pagon, Wallace, Bean, Stephens, and Amemiya (1993–2018).

Key: MELAS, mitochondrial encephalomyelopathy, lactic acidosis, and stroke-like episodes; MERRF, myoclonic epilepsy and ragged red fibers.

Tay-Sachs disease is an example of an autosomal recessive condition. It is caused by the absence of an enzyme, hexosaminidase A, which normally metabolizes a potentially toxic product of nerve cells (Kaback & Desnick, 2011). In affected children, this product cannot be broken down and is stored in the brain, leading to progressive brain damage and early death.

Alternate forms of the gene for hexosaminidase A are known to exist. The different forms of a gene, called **alleles**, include the normal gene, which can be symbolized by a capital “A” because it is dominant, and the mutated allele (in this example, carrying Tay-Sachs disease), which can be symbolized by the lowercase “a” because it is recessive (Figure 1.9). Upon fertilization, the embryo receives two genes for hexosaminidase A, one from the father and one from the mother. The following combinations of alleles are possible: **homozygous** (carrying the same allele) combinations, AA or aa, and **heterozygous** (carrying alternate alleles) combinations, aA or Aa. Because Tay-Sachs disease is a recessive disorder, two abnormal recessive genes (aa) are needed to produce a child who has the disease. Therefore, a child with aa would be homozygous for the Tay-Sachs mutation (i.e., have two copies of the mutated gene and manifest the disease), a child with aA or Aa would be heterozygous and a healthy carrier of the Tay-Sachs mutation, and a child with AA would be a healthy noncarrier.

If two heterozygotes (carrying alternate alleles) were to have children ($aA \times Aa$ or $Aa \times aA$), the following combinations could occur: AA, aA or Aa, or aa (Figure 1.9). According to the law of probability, each pregnancy would carry a one in four chance of the child

Figure 1.9. Inheritance of autosomal recessive disorders. Two copies of the abnormal gene (aa) must be present to produce the disease state: A) Two carriers mating will result, on average, in 25% of the children being affected, 50% being carriers, and 25% noncarriers; B) A carrier and a noncarrier mating will result in 50% noncarriers and 50% carriers and no children will be affected.

being a noncarrier (AA), a one in two chance of the child being a carrier (aA or Aa), and a one in four risk of the child having Tay-Sachs disease (aa). If a carrier has children with a noncarrier (aA $\times$ AA), each pregnancy carries a one in two chance of the child being a carrier (aA, Aa), a one in two chance of the child being a noncarrier (AA), and virtually no chance of the child having the disease (Figure 1.9). Siblings of affected children, even if they are carriers, are unlikely to produce children with the disease because this can only occur if they have children with another carrier, which is an unlikely occurrence in these rare diseases except in cases of intermarriage.

The one in four risk when two carriers have children is a probability risk. This does not mean that if a family has one affected child the next three will be unaffected. Each new pregnancy carries the same one in four risk; the parents could, by chance, have three affected children in a row or five unaffected children. In the case of Tay-Sachs disease, carrier screening is used to identify at-risk couples and prenatal diagnosis to provide information about whether the fetus is affected (see Chapter 3).

Because it is unlikely for a carrier of a rare condition to have children with another carrier of the same disease, autosomal recessive disorders are quite rare in the general population, ranging from 1 in 2,000 to 1 in 200,000 or fewer births (McKusick-Nathans Institute of Genetic Medicine & The National Center for Biotechnology Information, 2017). When a union occurs within an extended family, also called consanguinity (e.g., cousin marriage; Figure 1.10) or when unions among ethnically, religiously, or geographically isolated populations occur, the incidence of these disorders increases markedly. Some ethnic populations have higher carrier frequency than others; for example, carrier frequency for cystic fibrosis in people of Northern European background is 1 in 28, but for Asians, the carrier frequency is 1 in 118 (Ong et al., 2017).

Like Tay-Sachs disease, certain other autosomal recessive disorders are caused by mutations that lead to an enzyme deficiency of some kind. In most cases, there are a number of different mutations within the gene that can produce the same disease. Because these enzyme

Figure 1.10. A family tree illustrating the effect of consanguinity (in this case, a marriage between first cousins) on the risk of inheriting an autosomal recessive disorder. The chance of both parents being carriers is usually less than 1 in 300. When first cousins conceive a child, however, the chance of both parents being carriers rises to 1 in 8. The risk, then, of having an affected child increases almost 40-fold.

deficiencies generally lead to biochemical abnormalities involving either the insufficient production of a needed product or the buildup of toxic materials, **developmental disabilities** or early death may result (see Chapter 16). Autosomal recessive disorders affect males and females equally, and there tends to be clustering in families (i.e., more than one affected child per family). However, a history of the disease in past generations rarely exists unless there has been intermarriage.

Autosomal Dominant Disorders Over 1,000 autosomal dominant disorders have been identified, the most common ones having a frequency of 1 in 200 births (Youngblom et al., 2016). Autosomal dominant disorders are quite different from autosomal recessive disorders in mechanism, incidence, and clinical characteristics (Table 1.3). Because autosomal dominant

Table 1.3. Comparison of autosomal recessive, autosomal dominant, and X-linked inheritance patterns

	Autosomal recessive	Autosomal dominant	X-linked
Type of disorder	Enzyme deficiency	Structural abnormalities	Mixed
Examples of disorder	Tay-Sachs disease Phenylketonuria (PKU)	Achondroplasia Neurofibromatosis	Fragile X syndrome Muscular dystrophy
Carrier expresses disorder	No	Yes	Sometimes
Increased risk in other family members from intermarriage/consanguinity	Yes	No	No

disorders are caused by a single abnormal allele, individuals with the **genotypes** Aa or aA are both affected to some degree.

To better understand this, consider NF1, the neurological disorder discussed previously. Suppose a represents the normal recessive gene and A indicates the mutated dominant gene for NF1. If a person with NF1 (aA or Aa) has a child with an unaffected individual (aa), there is a one in two risk, statistically speaking, that the child will have the disorder (aA or Aa) and a one in two chance he or she will be unaffected (aa ; Figure 1.11). An unaffected child will not carry the abnormal allele and therefore cannot pass it on to his or her children.

Autosomal dominant disorders affect men and women with equal frequency. They tend to involve physical impairments (tumors in the case of NF1) rather than enzymatic defects. In affected individuals, there is often a family history of the disease; however, approximately half of affected individuals represent a new mutation. Although individuals with a new mutation will risk passing the mutated gene to their offspring, their parents are unaffected and at no greater risk than the general population of having a second affected child. In some cases, a mutation occurs early in the development of eggs and sperm. This is called germline, or gonadal, mosaicism and is estimated to occur approximately 1.3% of the time. If gonadal mosaicism is present in a parent, theoretically two siblings can be

affected with the same condition and neither parent appears to be affected (Rahbari et al., 2015). There can also be partial penetrance of the gene, which produces a less severe disorder (e.g., in NF1 or tuberous sclerosis), or a delayed onset form of the disease (e.g., in Huntington disease).

X-Linked Disorders Unlike autosomal recessive and autosomal dominant disorders, which involve genes located on the 22 non-sex chromosomes (autosomes), X-linked (previously called sex-linked) disorders involve mutant genes located on the X chromosome. X-linked disorders primarily affect males (Genetics Home Reference, 2017a). The reason for this is that males have only one X chromosome; therefore, a single dose of the abnormal gene causes disease. Because females have two X chromosomes, a single recessive allele usually does not cause disease provided there is a normal allele on the second X chromosome (Figure 1.12). Approximately 1,000 X-linked disorders have been described, including Duchenne muscular dystrophy and hemophilia (McKusick-Nathans Institute of Genetic Medicine & The National Center for Biotechnology Information, 2017). Carrier mothers in two-thirds of the cases pass on these disorders from one generation to the next; one-third of these cases represent new mutations.

As an example of an X-linked disorder, children with Duchenne muscular dystrophy develop a

Figure 1.11. Inheritance of autosomal dominant disorders. Only one copy of the abnormal gene (A) must be present to produce the disease state: A) If an affected person conceives a child with an unaffected person, statistically speaking, 50% of the children will be affected and 50% will be unaffected; B) If two affected people have children, 25% of the children will be unaffected, 50% will have the disorder, and 25% will have a severe (often fatal) form of the disorder as a result of a double dose of the abnormal gene.

Figure 1.12. Inheritance of X-linked disorders: A) A carrier woman has a child with an unaffected man. Among the female children, statistically speaking, 50% will be carriers and 50% will be unaffected. Among the male children, 50% will be affected and 50% will be unaffected; B) A carrier woman has a child with an affected man. Of the female children, 50% will be carriers and 50% will be affected. Of the male children, statistically speaking, 50% will be unaffected and 50% will be affected.

progressive muscle weakness (Bushby et al., 2010a, 2010b; Suthar & Sankhyan, 2017). The disease results from a mutation in the dystrophin gene (located on the X chromosome), the function of which is to ensure stability of the muscle cell membrane. Because the disease affects all muscles, eventually the heart muscle and the diaphragmatic muscles needed for circulation and breathing respectively are impaired. Dystrophin is also required for typical brain development and function, so affected boys may have cognitive impairments.

In fact, approximately 10% of males with intellectual disability and 10% of females with learning disabilities are affected by X-linked conditions (Inlow & Restifo, 2004). Males are more than twice as likely to have intellectual disability than females. This finding is attributable to a combination of factors: first, X-linked disorders affect males disproportionately more than females, and second, there is an unusually large number of genes residing on the X chromosome that are critical for normal brain development, nerve cell function, learning, and memory. Up to 10% of all known genetic errors causing intellectual disability are on the X chromosome despite the X chromosome containing only 4% of the human genome.

The mechanism for passing an X-linked recessive trait to the next generation is as follows: Women who have a recessive mutation (Xa) on one of their X chromosomes and a normal allele on the other (X) are carriers of the gene (XaX). Although these women are usually clinically unaffected, they can pass on the abnormal gene to their children. Assuming the father is unaffected, each female child born to a carrier mother has a one in two chance of being a carrier (i.e., inheriting the mutant Xa allele from her mother and the normal X allele from her father; Figure 1.12). A male child (who has only one X chromosome), however, has a one in two risk of having the disorder. This occurs if he inherits the X chromosome containing the mutated gene (XaY) instead of the normal one (XY). A family tree frequently reveals that some maternal uncles and male siblings have the disease. X-linked disorders are never passed from father to son because boys inherit their Y chromosome from their father and their X chromosome from their mother.

Occasionally, females are affected by X-linked diseases. This can occur if the woman has adverse **lyonization** (inactivation of one of the X chromosomes) or if the disorder is X-linked “dominant.” Regarding the former mechanism, the geneticist Mary Lyon questioned why women have the same amount of X chromosome-directed gene product as men instead of twice as much, as would be predicted from their genetic makeup. Dr. Lyon postulated that early in embryogenesis, one of the two X chromosomes in each

cell is inactivated, making every female fetus a mosaic. This implied that some cells would contain an active X chromosome derived from the father, whereas others would contain an active X chromosome derived from the mother. This “lyonization” hypothesis was later proven to be correct. In most instances, the cells in a woman’s body have a fairly equal division between maternally and paternally derived active X chromosomes. In a small fraction of women, however, the distribution is very unequal. If the normal X chromosome is inactivated preferentially in cells of a carrier of an X-linked disorder, the woman will manifest the disease, although usually in a less severe form than the male. An example is OTC deficiency, the disorder Katy had in this chapter’s opening case study (see also Chapter 16).

The second mechanism for a female to manifest an X-linked disorder is if the disorder is transmitted as X-linked dominant. Although most X-linked disorders are recessive, a few appear to be dominant. One example is Rett syndrome (Chahrour & Zoghbi, 2007; Liyanage & Rastegar, 2014; Matijevic, Knezevic, Slavica, & Pavelic, 2009; Percy, 2008). It appears that in this disorder, the presence of the mutated transcription gene *MECP2* on the X chromosome of a male embryo nearly always leads to lethality. When it occurs in one of the X chromosomes of the female, however, it is compatible with survival but results in a syndrome marked by microcephaly, developmental regression, intellectual disability, and autism-like behaviors. That is why virtually all children with Rett syndrome are girls.

Mitochondrial Inheritance

Each cell contains several hundred mitochondria in its cytoplasm (Figure 1.1). Mitochondria produce the energy needed for cellular function through a complex process termed **oxidative phosphorylation**. It has been proposed that mitochondria were originally independent microorganisms that invaded our bodies during the process of human evolution and then developed a symbiotic relationship with the cells in the human body. They are unique among cellular **organelles** (the specialized parts of a cell) in that they possess their own DNA, which is in a double-stranded circular pattern rather than the double-helical pattern of nuclear DNA and contains genes that are different from those contained in nuclear DNA (Figure 1.13). Most of the proteins necessary for mitochondrial function are coded by nuclear genes, and disorders caused by abnormalities in these genes are most often inherited in an autosomal recessive manner. Certain mitochondrial functions, however, are dependent on genes encoded on the mitochondrial DNA. A mutation in

Figure 1.13. Mitochondrial DNA genome. The genes code for various enzyme complexes involved in energy production in the cell. The displacement loop (D loop) is not involved in energy production. (This figure was published in *Medical genetics*, revised 2nd edition, by Jorde, L.B., Carey, J.C., & Bamshad, M.J., et al., p. 105, Copyright C.V. Mosby [2001]; adapted by permission.) (Key: ■ Complex I genes [NADH dehydrogenase], ■ Complex III genes [ubiquinol: cytochrome c oxidoreductase], □ tRNA genes, ■ Complex IV genes [cytochrome c oxidase], ■ Complex V genes [ATP synthase], ■ ribosomal RNA genes.)

a mitochondrial gene can result in defective energy production and a disease state, particularly affecting organs with high energy demands, such as the heart, skeletal muscle, and brain (Gorman, 2016). An example of a disorder with mitochondrial inheritance is mitochondrial encephalomyelopathy, lactic acidosis, and stroke-like episodes (MELAS), a progressive neurological disorder marked by episodes of stroke and dementia. Other disorders with mitochondrial inheritance can lead to blindness, deafness, or muscle weakness. There are hundreds of mitochondrial diseases, some of which have clear genetic causes, while others do not. Every cell contains many mitochondria, but not every mitochondrion may carry a given mutation. In many disorders that are inherited through the mitochondrial genome, there is great clinical variability based on the **heteroplasmy** or the mix of different mitochondrial genomes within a single individual. There may be significant variability among specific tissues in an individual; some organs or tissues may be affected by the mitochondrial disorder and others may not.

Because eggs, but not sperm, contain cytoplasm, mitochondria are inherited from one's mother. As a result, mitochondrial DNA disorders are passed on from generally unaffected mothers to their children, both male and female (Figure 1.14). Men affected by a mitochondrial disorder cannot pass the trait to their children. In some cases, a mother with significant heteroplasmy may have only mild effects of a disease but may pass on only mutated mitochondrial genomes to a child. In that case, a child would have a homoplasmic mitochondrial mutation and would have a much more severe clinical course.

Trinucleotide Repeat Expansion Disorders

There has been an increased recognition that **copy number variability** accounts for several developmental disabilities (Sansović, Ivankov, Bobinec, Kero, & Barišić, 2017). One particular type of copy number variation is the trinucleotide repeat expansion (triplet repeat disorder), which has been linked to a number of disorders that do not follow typical Mendelian inheritance. Trinucleotide repeat disorders result from problems in recombination and replication during meiosis. Certain genes have highly repetitive sequences of trinucleotides. These repetitive sequences may expand (or contract) in size during meiosis. Once the repetitive sequence reaches a certain size threshold, it may interfere with the function of the gene and lead to a clinically apparent disorder. The expansion length is linked to the phenotype, with the longer expansions often presenting with earlier and more severe clinical signs and symptoms.

The first triplet repeat disorder discovered was fragile X syndrome, the most common inherited cause of intellectual disability. Boys and girls with fragile X syndrome have a phenotype that includes

Figure 1.14. Mitochondrial inheritance. Because mitochondria are inherited exclusively from the mother, defects in mitochondrial disease will be passed on from the mother to her children, as illustrated in this pedigree.

a characteristic physical appearance, cognitive skills impairments, and impaired adaptive behaviors (Chonchaiya, Schneider, & Hagerman, 2009; Schneider, Hagerman, & Hessel, 2009; also see Chapter 15). Many affected children satisfy the criteria for the diagnosis of autism. The prevalence of fragile X syndrome (the full mutation) for males is about 1 in 3,600. The prevalence of the full mutation in females is estimated to be at least 1 in 4,000 to 1 in 6,000. Fragile X syndrome arises from an expansion of the number of cytosine-guanine-guanine (CGG) trinucleotide repeats occurring within the fragile X mental retardation protein (FMR1) gene. Inheritance of the instability in CGG regions leads to expansion from the normal number of repeats (6–40) to a premutation state (50–200 repeats) or from a premutation state to full mutation (>200 repeats). The stability of the CGG repeat depends upon the length of the repeat, as well as the sex of the individual passing on the mutation. The increased risk of CGG expansion from one generation to another is a phenomenon termed **anticipation**. Anticipation leads to an increasingly severe clinical phenotype in successive generations. When a child is suspected of having fragile X syndrome, the diagnosis can be confirmed by detecting the number of trinucleotide repeats in FMR1 using a clinically available molecular genetic blood test (Collins et al., 2010). There is a correlation between the number of trinucleotide repeats and the severity of disease. Other trinucleotide repeat disorders include myotonic dystrophy and Huntington's disease.

EPIGENETICS

The diagnostic evaluation of children with intellectual disability and other developmental disabilities has become increasingly complex in recent years due to a number of newly recognized genetic mechanisms and the availability of sophisticated methods to diagnose them. It has been appreciated that changes in gene expression can occur by mechanisms that do not permanently alter the DNA sequence (Urduingio, Sanchez-Mut, & Esteller, 2009), a phenomenon termed **epigenetics**. Epigenetic mechanisms are important regulators of biological processes because they include genome reprogramming during embryogenesis (Kumar, 2008). Epigenetic modification, which is important in developmental processes, may have long-term effects on learning and memory formation. Epigenetic impairments may result from dysfunction of certain enzymes, genomic imprinting, and triplet repeat copy number variation. A number of conditions causing developmental disabilities, including fragile X syndrome, Rett syndrome, Rubinstein-Taybi syndrome, Prader-Willi syndrome, and VCFS, can be attributed to disruptions in

epigenetic function. It is interesting to note that virtually all epigenetic disorders have been found to have a high incidence of symptoms consistent with autism spectrum disorder or other neurodevelopmental disorders (Moss & Howlin, 2009). In addition, the risk of epigenetic disorders has been found to be increased in pregnancies assisted by *in vitro* fertilization (Lazaraviciute, Kauser, Bhattacharya, Haggarty, & Bhattacharya, 2014).

According to Mendelian genetics, the **phenotype**, or appearance of an individual should be the same whether the given gene is inherited from the mother or the father. This is not always the case, however, because of **genomic imprinting**. This is an epigenetic phenomenon in which the activity of the gene is modified depending upon the sex of the transmitting parent (Genetics Home Reference, 2017b). Most autosomal genes are expressed in both maternal and paternal alleles. However, imprinted genes show expression from only one allele (the other is silenced or used differently), and this is determined during production of the egg or sperm. Imprinting implies that the gene carries a “tag” placed on it during spermatogenesis or oogenesis. This is most often accomplished by adding methyl groups to the DNA, affecting the expression of the methylated genes. Imprinted genes are important in development and differentiation, and if expression from both alleles is not maintained, disturbances in development can result (Soellner et al., 2017).

The first human imprinting disorder discovered was Prader-Willi syndrome. It is caused by a paternal deletion in chromosome 15 or by maternal uniparental disomy in which both chromosome 15s come from the mother. It can also result if both copies of chromosome 15 are imprinted as if they came from the mother regardless of the actual parent of origin (Conlin et al., 2010; Driscoll, Miller, Schwartz, & Cassidy, 2017). Prader-Willi syndrome is characterized by severe hypotonia and feeding difficulties in early childhood, followed by an insatiable appetite and obesity by school age. It features significant motor and language delays in the first 2 years of life; borderline to moderate intellectual disability; and severe behavioral problems, including compulsive and hoarding behaviors. Many affected children satisfy the criteria for the diagnosis of autism (Driscoll et al., 2017; Goldstone, Holland, Hauffa, Hokken-Koelega, & Tauber, 2008). Other examples of imprinted neurogenetic disorders include Angelman syndrome and Beckwith-Wiedemann syndrome (Dan, 2009; Gurrieri & Accadia, 2009; Soellner et al., 2017).

GENETIC TESTING

Genetic tests have been developed for many of the roughly 7,000 rare diseases identified, including all

those described in this chapter. Most tests look at single genes and are used to diagnose rare genetic disorders, such as fragile X syndrome and Duchenne muscular dystrophy. In addition, some genetic tests look at rare inherited mutations of otherwise protective genes that are responsible for some hereditary breast and ovarian cancers. An increasing number of tests are being developed to look at multiple genes that may increase or decrease a person's risk for developing common diseases, such as cancer or diabetes. In addition, pharmacogenetic tests may be used to help identify genetic variations that influence a person's response to medicines. Here, we will focus on genetic testing used in diagnosing causes of developmental disabilities.

There are three types of genetic testing currently being used to detect genomic-based causes of developmental disabilities: **chromosomal microarray analysis**, **next-generation sequencing**, and **whole-exome/genome sequencing**. Chromosomal microarrays use probes to test for known DNA sequences and can identify disorders where the specific genetic abnormality is

caused by a microdeletion or microduplication, as seen in Williams syndrome or chromosome 15q duplication syndrome. Microarrays cannot be used to identify mutations (alterations of a single nucleotide, such as a point mutation) in a gene. In general, a chromosomal microarray is the first-line test recommended for a child presenting with developmental delays or autism (see Box 1.1). The second type of genetic testing, next-generation sequencing, allows detection of mutations in single genes, such as *NF1* associated with neurofibromatosis type 1, or *CFTR*, in which two mutations are needed to cause cystic fibrosis. The final approach is whole-exome/genome sequencing and may be used in a case where no genetic cause has been identified for the child's phenotype. Whole-exome sequencing is typically utilized when a child's clinical history is suspicious for a genetic condition based on the presence of multiple congenital anomalies, developmental delays, or other undiagnosed issues. Here, exome sequencing (sequencing the entire exome) can help identify alterations in genes all at once rather than looking at

BOX 1.1 EVIDENCE-BASED PRACTICE

Autism and Genetic Testing

Autism spectrum disorder (ASD) is a highly variable group of neurodevelopmental conditions. There is evidence that children with ASD more commonly have medical issues and/or physical differences and dysmorphic features. Because of this high level of variability, the genetic workup may differ depending on the child's clinical issues. Stratification of children with ASD can help to determine what type of genetic testing might be most appropriate for a patient. The general recommendation is that chromosomal microarray (CMA) is the first-line test for a child with ASD.

Tammimies et al. (2015) reported molecular diagnostic yields for CMA and whole-exome sequencing (WES) in a population of 258 children with ASD stratified by clinical features, including number and type of physical anomalies. Each child was classified as having essential, equivocal, or complex ASD based on their morphology score. The main outcomes measured were the clinical differences, the yield of molecular diagnosis from CMA and WES, and the differences in the diagnostic yields between the three categories.

Most of the patients had essential autism (approximately 70%), while approximately 20% had equivocal autism and approximately 10% were classified as complex. Of the 258 subjects, the WES diagnostic yield was 8.4% and the CMA yield was 9.3%. In children who received both tests, the diagnostic yield was 15.8%. In children with complex ASD, the molecular diagnostic yield was near 35% when both CMA and WES were performed. Age at diagnosis with ASD was also significantly older for this complex group. In the children with essential autism, the diagnostic yield was much lower when using both CMA and WES.

Points to Remember

- CMA should still be considered the first-line test for children with autism. A medical genetics evaluation should be completed **prior** to ordering any genetic testing.
- Medical genetics evaluation might help identify patients more likely to achieve a molecular diagnosis with genetic testing; complex patients might benefit from WES if properly counseled by a medical geneticist and genetic counselor.
- Patients with complex medical issues receive later diagnoses of autism; it is important to be aware of these symptoms and provide an autism evaluation when features are first noted.

each gene individually. It does this by selecting the approximately 180,000 exons that constitute about 1% of the human genome (or approximately 30 million base pairs) and then sequencing the DNA using a high-throughput DNA sequencing technology. This technique has been used to identify genetic variants seen in autism. Exome sequencing, however, is only able to identify those variants found in the coding region of genes that affect protein function. It is not able to identify structural and non-coding variants associated with disease; this can be found using whole-genome sequencing. Presently, whole-genome sequencing is typically not utilized in the clinical setting due to the high costs and time associated with sequencing full genomes. In addition to these challenges, our understanding of much of our genome is still in its infancy. As our knowledge continues to grow, clinicians will be able to more accurately interpret results and provide appropriate genetic counseling for families.

There are many other types of genetic tests available for specific disorders. For example, some inborn errors of metabolism can be identified by detecting the accumulation of specific compounds in blood, urine, or other tissue samples. Testing for methylation patterns on DNA samples detects certain epigenetic disorders. Other genetic disorders may be detected radiologically. The decision about which tests are most appropriate for a specific patient is complex, and physicians with expertise in medical genetics can help guide testing and interpret results. While some tests, such as karyotype analysis to detect large chromosome abnormalities or rearrangements (like those seen in Down syndrome and Klinefelter syndrome), are no longer commonly used during evaluation of a child with developmental delay, they may be appropriate depending on a child's clinical presentation. For example, a girl referred for mild developmental

delays, short stature, webbed neck, and a heart defect should first undergo a karyotype to evaluate for Turner syndrome; microarray and next-generation sequencing would not be the most appropriate initial tests for this patient. Medical geneticists and genetic counselors can help determine the correct test for a patient based on utility and cost effectiveness. They can also ensure that the patient is properly consented and understands the implications of these complex analyses (see Box 1.2).

ENVIRONMENTAL INFLUENCES ON HEREDITY

The particular genes that a person possesses determine his or her genotype, and the expression of the genes results in the physical appearance of traits—that is, the phenotype of the individual. For some traits and clinical disorders, however, the same genotype can produce quite different phenotypes depending on environmental influences. In terms of traits, bright parents tend to have bright children and tall parents tend to have tall children; however, the interaction of genetics with the prenatal and postnatal environments allows for many possible outcomes. For example, it has been found that, as a result of an increased protein intake during childhood, Asians who grow up in the United States are significantly taller than their parents who grew up in Asia. Disorders that have both genetic and environmental influences include diabetes, meningomyelocele, cleft palate, and pyloric stenosis (Au, Ashley-Koch, & Northrup, 2010). Considering the example of PKU, an affected child will develop intellectual disability if the PKU is not treated early but will have typical development if it is treated with a diet low in phenylalanine from infancy (Feillet et al., 2010; also see Chapter 16).

BOX 1.2 INTERDISCIPLINARY CARE

What Is a Genetic Counselor?

Genetic counselors are health care professionals with specialized, master's-level training in human genetics. They are an excellent resource for both patients and providers of children with rare diseases and developmental disabilities, as they are able to explain complex genetic ideas while also providing psychosocial support. Genetic counselors can guide patients on how inherited diseases might affect them or their families, analyze family histories, and help determine what kind of genetic testing might be most appropriate for a patient. In a pediatric setting, genetic counselors work alongside medical geneticists and are often the patient's point of contact within their team of genetic care providers. Genetic counselors also work with pregnant women, cancer patients, and people with more common conditions such as heart disease, diabetes, and Alzheimer's disease. Genetic counselors also meet with couples planning a pregnancy to help determine risks for future children. For more information or to find a genetic counselor, please visit www.nsgc.org.

GENETIC THERAPIES

A range of approaches is being used to treat genetic disorders. In the case of inborn errors of metabolism, treatment has focused on either replacing the deficient product of the defective enzyme (e.g., in thyroid hormone deficiency) preventing the accumulation of toxic material because the enzyme does not break it down or replacing the defective enzyme (see Chapter 16). Preventing accumulation of toxic metabolites often relies on dietary manipulation (e.g., PKU) or stimulation of an alternate pathway around the enzyme block (urea cycle disorders). In a few cases, enzyme replacement therapy is available (e.g., in Gaucher disease). Here the missing or defective enzyme is given intravenously at intervals to correct the metabolic defect. Bone marrow transplantation (e.g., in sickle cell disease) or liver transplantation (e.g., in OTC deficiency) has been used to correct other genetic disorders by replacing the organ that is producing the defective product with an organ that can produce a normal one. While these approaches to genetic disorders have improved outcomes in a number of disorders, they represent only a fraction of all the genetic causes of developmental disabilities and their cost can be up to \$500,000 per year.

More recently, the concepts of exon skipping, gene therapy, and gene editing have been advanced and are in clinical trials. In **exon skipping**, a form of RNA splicing is used to cause cells to “skip” over faulty sections of the genetic code, leading to a truncated but still functional protein despite the genetic mutation (Kole & Krieg, 2015). The first exon skipping drug was approved in 2016 for use in a subgroup of individuals with Duchenne muscular dystrophy who have a specific mutation. In **gene therapy**, copies of the normal gene are infused most commonly using a virus transporter in order to “replace” the defective gene. At the writing of this edition, the only approved gene therapy drugs are for cancer and HIV, although gene therapy clinical trials for several single gene defects causing developmental disabilities are currently in process. **Gene editing** is a form of gene therapy in which a technology called CRISPR/Cas9 is used to cut the gene at the point of the mutation and to replace it with a corrected gene sequence. The first successful case of gene editing in an embryo in the United States was reported in 2017 (Ma et al., 2017). Researchers targeted and edited a gene associated with cardiac disease at the level of the embryo. Although gene editing technology is available, many ethical considerations exist around this type of practice. Some argue that gene editing of an embryo allows prevention of serious genetic diseases, while others express concerns around creating “designer babies” or selecting traits such as desirable physical characteristics or gender.

SUMMARY

- Each human cell contains a full complement of genetic information encoded in genes contained in 46 chromosomes.
- The unequal division of the reproductive cells, the deletion of a part of a chromosome, the mutation in a single gene, or the modification of gene expression can each lead to developmental disabilities.
- There are numerous genetic tests available to diagnose many of these genetic disorders.
- Early identification may lead to improved outcome as a result of therapies that are now available for certain rare genetic disorders associated with developmental disabilities.

CHAPTER 2

Environmental Exposures

Shruti N. Tewar

Upon completion of this chapter, the reader will be able to

- Explain the history of environmental exposures in childhood
- Discuss individual environmental toxicants from the perspectives of epidemiology, mechanism of toxicity, and effect on brain development
- Describe screening and prevention strategies for environmental toxicant exposure
- Understand how environmental toxicants influence epigenetic changes and impact development
- Discuss the societal financial implications and cost of environmental toxicant exposure
- Describe prevention and public policy regarding environmental exposures

The world has undergone incredible advances over the last two centuries, beginning with the Industrial Revolution, which drove changes in agriculture, transportation, and manufacturing and led to urbanization. This industrialization also necessitated the large-scale production of chemicals to build stronger, better materials used in manufacturing with diverse applications. Today, there are more than 80,000 chemicals in commercial use; unfortunately, roughly 1,000 of these have been identified as toxins. Some are teratogenic, leading to physical malformations due to *in utero* exposures, and others are neurotoxic, resulting in developmental disabilities from postnatal exposure. The twentieth century was marked by a number of catastrophes caused by environmental

toxins that have affected children and led to developmental disabilities. In addition, low-level exposures to a number of environmental toxicants have been shown to be associated with low birth weight, preterm births, failure to thrive, asthma, obesity, cognitive impairments, learning disabilities, and other neurodevelopmental disorders, including attention-deficit/hyperactivity disorder (ADHD) (Baghurst et al., 1992; Bellinger, Stiles, & Needleman, 1992; Lanphear et al., 2005).

■ ■ ■ CASE STUDY

Jaylen is a 6-year-old boy. At a well-child visit, his mother shared her concern that he is struggling at

Acknowledgments: I am very grateful to Dr. Mirko von Elstermann, Biomedical Sciences Librarian at the University of Iowa's Hardin Library for the Health Sciences, for his support in finding relevant toxicant literature.

school. He is very active and cannot sit and participate in learning like most children in his class. He can sing the ABCs but cannot identify letters or write his first and last name. Jaylen's birth and early development were uncomplicated per parent report, with developmental milestones achieved on time. His lead levels at 12 months and 24 months were less than 5 mcg/dL (normal). However, he was screened again at 4 and 5 years of age for lead poisoning due to concerns about lead contamination in the drinking water. His venous lead levels were 28 mcg/dL at 4 years and 25 mcg/dL at 5 years of age, both elevated. While the local municipality addresses the lead contamination in the drinking water, since Jaylen's lead level is greater than 15 mcg/dL, his pediatrician has recommended switching to bottled water with plans to monitor his lead levels every 3 months until they are below the reference range of 5 mcg/dL.

Thought Questions:

What other professionals will need to be involved in Jaylen's health and development going forward? What are some long-term effects of lead poisoning? Are they reversible once the lead level returns to an acceptable range?

A HISTORICAL PERSPECTIVE

As more and more chemicals were invented and produced on a large scale, there was an increased awareness of the potentially toxic effects of these chemicals to the human population, especially to young children and women of childbearing age. The most devastating of these toxic exposures have been lead, methylmercury, thalidomide, and isocyanate gas:

- Lead (in the form of lead paint) was the first identified environmental toxin to affect children, described in 1904 by an Australian pediatrician, J. Lockhart Gibson (Gibson, 2005). Affected children presented clinically with severe anemia, paralysis, blindness, and occasionally death. In 2015, a state of emergency was declared in Genesee County, Michigan, when extremely high lead levels were detected in the water supply for the city of Flint after the city switched its water supply source without using adequate measures to prevent corrosion and leaching from lead pipes. As a result, the children living in Flint who were exposed to the untreated water were noted to have significantly elevated lead levels after the switch (Hanna-Attisha, LaChance, Sadler, & Champney Schnepf, 2015).

- In 1956, methylmercury poisoning was identified as the cause of sensory disturbances, ataxia, dysarthria, constriction of the visual field, auditory disturbances, and tremor in individuals eating contaminated fish from Minamata Bay, Japan (Harada, 1995). Furthermore, when pregnant women ate the fish, their fetuses were found to be poisoned by the methylmercury and to have sustained extensive brain damage.
- In 1961, thalidomide, which was used to treat morning sickness in pregnant women, was found to induce severe limb defects (phocomelia) in the fetus (Neil, 2015). Over 10,000 children were born with a range of severe and debilitating malformations.
- In 1984, a leak at a pesticide plant in Bhopal, India, led to over 500,000 people being exposed to methyl isocyanate gas. It affected more than 200,000 children, causing respiratory, neurologic, psychiatric, and ophthalmic symptoms (Mishra et al., 2009). For women who were pregnant at the time, more than one-half of their progeny were still born or did not survive the first 30 days of life, and several children were born with birth defects (Varma, 1987).

As a result of these tragedies, the role of environmental toxins on child health and development became more prominently recognized.

THE DEVELOPING BRAIN AND TOXIC EXPOSURE

Environmental toxins affect the brain and body of children through multiple routes; they are ubiquitous in air, dust particles, water, and contact surfaces. Some of the common routes of exposure are through ingestion, inhalation, skin contact, and placental transfer. The fetus is particularly susceptible to environmental exposures, beginning with conception and continuing during the rapid phase of cell differentiation, proliferation, and migration (see Chapter 6). The placenta does not provide a significant barrier against environmental toxins. In fact, in the case of methylmercury, the fetus was found to be exposed to even larger doses than the mother (Ramirez, Cruz, Pagulayan, Ostrea, & Dalisay, 2000). Additionally, the fetus may lack critical enzymes necessary to metabolize and rid the body of certain toxins, such as pesticides including isocyanate (Chen, Chang, Tao, & Lu, 2015). Younger children also have a greater risk for toxic exposure due to higher hand-to-mouth activity, increased absorption rates, and an immature blood-brain barrier. Furthermore, their bodies are not efficient at removing some of the toxins, leading to accumulation in the body over time.

TIMING OF VULNERABILITY TO ENVIRONMENTAL TOXINS

The effects of environmental toxins vary based on the timing of the exposure during fetal development. In the first and second trimesters, environmental toxins can interfere with cell migration, differentiation, and proliferation through placental transfer. This can lead to physical deformities as well as impact brain development. As examples, thalidomide is teratogenic in the first trimester during the period of limb formation, whereas methyl mercury and polychlorinated biphenyls (PCBs) affect synaptogenesis (see Chapter 8) throughout pregnancy. Although environmental exposure to toxins does not cause physical defects after birth, it can significantly affect postnatal brain development. In this context, lead exposure interferes with pruning and myelination in the brain, which continues throughout early childhood.

SPECIFIC NEUROTOXICANTS

The following section describes specific neurotoxicants and their effects on fetal and child development, including lead, tobacco, mercury, alcohol, polychlorinated biphenyls, and endocrine disruptors. Table 2.1 summarizes these neurotoxicants, their common adverse effects, and recommendations for evaluation, prevention, and management.

Lead

Lead is the most commonly studied and best known neurotoxicant. It is commonly found in pipes, storage batteries, weights, ammunition, cable covers, paints, dyes, ceramic glazes, and caulk. Although it has been known to be neurotoxic since the early 1900s, lead-containing paint was not banned for interior use until 1978 and lead as an additive to gasoline was only removed in 1996 in the United States. Since then, the amount of lead released into the environment has been significantly reduced. However, lead that falls to the ground as dust; chipping lead paint from buildings and bridges; leaching of lead from landfills; disposal of lead containing products in landfills; industrial activities, such as ore mining, battery production, or ammunition manufacturing; and the corrosion of lead pipes can all result in the seepage of lead into the ground water.

Children are most commonly exposed to lead by eating foods or water contaminated with lead, or by ingesting or inhaling lead dust particles or paint chips. Lead poisoning can lead to a multitude of health problems, including anemia, kidney damage,

neurocognitive impairments, and peripheral neuropathy. Young children are at a higher risk for lead toxicity due to increased hand-to-mouth behaviors, higher respiratory rates, and increased absorptive capacity compared with older children and adults. There are multiple studies demonstrating the neurotoxic effects of lead on brain development (Bellinger et al., 1992; Braun, Kahn, Froehlich, Auinger, & Lanphear, 2006; Lanphear et al., 2005).

Increasingly, the effects on brain development of even low levels of lead exposures have been identified; no amount of lead exposure is deemed safe in children. Low-level lead exposure has been associated with an increased risk of cognitive impairment, impairments in memory, ADHD, and learning difficulties (Canfield et al., 2003; Evens et al., 2015; Jusko et al., 2008; Kim et al., 2010; Mason, Harp, & Han, 2014). Lanphear and colleagues (2005) demonstrated that an increase of blood lead concentration from less than 1 µg/dL to 10 µg/dL was associated with a 6.9-point decrease in IQ. While a 5-point change in IQ may not seem very large for an individual child, a 5-point decrease in the mean population IQ can have a substantial impact. It results in a 57% increase in children with an IQ less than 70 (Gilbert & Weiss, 2006) and an increased need for special education and other supports.

Animal studies have shown that lead disrupts neurotransmission, synaptogenesis, synaptic trimming, and myelination (Baranowska-Bosiacka et al., 2017; Gassowska et al., 2016; Lidsky & Schneider, 2006; Neal & Guilarte, 2010; Toscano & Guilarte, 2005). Lead also has been shown to alter gene expression within the brain, leading to inflammatory damage (Kidd, Anderson, & Schneider, 2008; Raciti & Ceccatelli, 2017; Schneider, Anderson, Kidd, Sobolewski, & Cory-Slechta, 2016).

In 2012, the Centers for Disease Control and Prevention (CDC) concluded that there is no safe level of lead exposure. **Chelation therapy**, a medical procedure to remove heavy metals from the body, is recommended when blood lead levels are greater than or equal to 45 µg/dL. Chelation therapy, however, does not reverse existing neurocognitive defects. Prevention of lead exposure is the best recommendation to protect against its effects on the developing brain.

Tobacco Smoke

Maternal smoking of tobacco during pregnancy and postnatal environmental tobacco exposure are associated with several adverse health outcomes in children. The effect of tobacco on the fetus is related to its active ingredient, nicotine, which crosses the placenta into the fetal circulation. Nicotine decreases

Table 2.1. Specific neurotoxicants, common adverse effects, and recommendations

Neurotoxicant	Common adverse effects	Recommendations
Lead	Low level exposure: Nausea, vomiting, anemia, abdominal pain, constipation, developmental delay, cognitive deficits, ADHD High lead levels: altered mental status, seizures, difficulty walking, coma and death	Lead monitoring, screening, and abatement Blood lead > 5 mcg/dL – 45 mcg/dL: close monitoring Blood lead > 45 mcg/dL: chelation
Tobacco smoke	Low birth weight Preterm labor and birth Increased risk of SUID, asthma, allergies, ADHD, intellectual disability, sleep problems, behavioral problems	Reduce secondhand smoke exposure Pregnant women should quit smoking
Methyl mercury	Sensory disturbances of vision, hearing, and touch Tremors Brain damage Microcephaly Cerebral palsy Seizures Cognitive impairment	Women who are pregnant, nursing, and of childbearing age and young children should avoid predatory fish with high mercury content in diet
Alcohol	Atypical facial features Microcephaly Short stature Cognitive deficits, attention and memory deficits, executive function deficits, cognitive impairment Speech and language disorders Learning disabilities Vision and hearing impairments	No alcohol consumption during pregnancy
Pesticides	Developmental delay Cognitive deficits ADHD Delayed social development and autism-like behaviors Respiratory problems Childhood cancers	Limit indoor and outdoor pesticide use Use comprehensive pest management Monitor water sources for high pesticide content in agricultural communities
Polychlorinated biphenyls (PCBs)	Low birth weight Cognitive delays Attention problems and impulsivity Obesity Decreased immunity Childhood cancers Delayed social skills with autism-like behaviors	Dispose of PCB-containing products safely Women who are pregnant, nursing, and of childbearing age and young children should avoid farm-raised salmon
Endocrine disruptors	Obesity Cognitive deficits ADHD Sex-specific changes in hormone levels Anxiety Social skill deficits	Choose BPA-free and/or phthalate-free plastics Avoid heating plastic containers with food

Key: ADHD, attention-deficit/hyperactivity disorder; SUID, sudden unexplained infant death; BPA, bisphenol A.

oxygen delivery, increases resistance to blood flow, and decreases the nutrient supply. Fetal exposure to nicotine has been shown to cause atypical cell proliferation, differentiation, and synaptic activity in the brain (Ino, 2010). The result is an increased risk of low birth weight (<2,500 gm) and preterm births. Maternal smoking also has been shown to affect brain development and vision. Furthermore, fetal exposure increases the risk of obesity, hypertension, asthma, and impaired lung function in children and adolescents up to 18 years of age

(Banderali et al., 2015; Clifford, Lang, & Chen, 2012; Weng, Redsell, Swift, Yang, & Glazebrook, 2012).

Postnatally, second-hand smoke exposure is associated with an increased risk of sudden infant death syndrome (SIDS), neurodevelopmental and behavioral disorders such as ADHD, conduct disorder, intellectual disability, sleep disruption, and respiratory disorders such as asthma and allergies (Banderali et al., 2015; Froehlich et al., 2009; Hughes et al., 2017; Poole-Di Salvo, Liu, Brenner, & Weitzman, 2010; Zhou et al., 2014).

Mercury

Mercury is released into the environment from rock, burning of fossil fuels, and incineration of consumer products containing mercury (e.g., electronic devices, batteries, light bulbs, and thermometers). Mercury is toxic in both its elemental and inorganic forms. The elemental form gets vaporized and can be inhaled, and the inorganic form is converted by naturally occurring biologic processes into organic methylmercury, which is highly toxic.

Methylmercury can be concentrated in the aquatic food chain; as such, human consumption of seafood is a major route of exposure. Methyl mercury crosses the placental barrier easily, and because the fetal blood-brain barrier is not fully developed, prenatal exposure can result in severe brain damage, microcephaly, seizures, cerebral palsy, and cognitive impairment (Boucher et al., 2012; Debes, Weihe, & Grandjean, 2016; Grandjean, Weihe, Debes, Choi, & Budtz-Jorgensen, 2014; Harada, 1995). Low levels of methylmercury exposure have been associated with decrements in IQ and deficiencies in visual spatial processing, memory, attention, and language (Boucher et al., 2012; Grandjean et al., 2014). The mechanism of action for methylmercury neurotoxicity is dependent on the timing and dose of exposure and includes widespread damage to the blood-brain barrier, neuronal cell damage/death, interference with neuronal migration, and alterations

in brain neurotransmitters (Antunes dos Santos et al., 2016). Currently, it is believed that the benefits of eating fish and other seafood outweigh the risks of methylmercury toxicity. It is recommended, however, that young children and women of childbearing age avoid fish that may contain high levels of mercury (U.S. Food & Drug Administration, 2017a).

Ethylmercury is a metabolite of thimerosal, a mercury-containing chemical used as a preservative in multidose vials of some vaccines. After the publication of a fraudulent (and subsequently retracted) article (Murch, 2004) purporting a linkage between thimerosal in the MMR vaccine and autism, many parents became concerned about giving vaccines to their children. Subsequently, numerous epidemiologic studies have shown there to be no evidence that thimerosal in vaccines is linked to autism (American Academy of Pediatrics, 2013). There is, in fact, a robust body of peer-reviewed, scientific studies done in the United States and other countries supporting the safety of thimerosal-containing vaccines (U.S. Food & Drug Administration, 2017b; World Health Organization, 2006). Currently, with the use of single-dose vials, all routinely recommended vaccines for infants in the United States are available as thimerosal-free preparations or contain less than 1 µg mercury/dose of thimerosal. Evidence-based practice Box 2.1 presents a discussion of thimerosal in vaccines and autism.

BOX 2.1 EVIDENCE-BASED PRACTICE

Vaccines and Autism

Ethylmercury is a metabolite of thimerosal, a mercury-containing chemical used as a preservative in multidose vials of some vaccines. Ethylmercury is different from methylmercury, which is associated with long-term neurologic effects of mercury poisoning. Since the publication of a fraudulent study in 1998, questions have been raised regarding the relationship between autism and vaccines, particularly the measles, mumps, rubella (MMR) combination vaccine. Parents have also raised concerns about too many vaccines overwhelming the immune system when given simultaneously.

These concerns have been shown to be invalid. The preservative thimerosal was never present in the MMR vaccine even though it was used in other vaccines in the 1990s. Furthermore, the American Academy of Pediatrics examined the available studies and published evidence that vaccines including the MMR were not associated with or caused autism and that children with delayed immunizations showed no benefits of delaying immunizations in the first year of life (American Academy of Pediatrics, 2013).

Application to Practice

- Clinicians should be aware of available evidence refuting the link between vaccines and autism.
- Clinicians should discuss the importance of vaccines and provide appropriate education to vaccine hesitant parents. It is important to revisit this discussion multiple times if necessary at each clinical encounter.
- Clinicians should be aware of resources and educational materials that can be shared with families about the safety of vaccines.

Alcohol

Alcohol is a known **teratogen**, and prenatal exposure to alcohol has been associated with a range of physical and neurodevelopmental disabilities covered under the umbrella term of **fetal alcohol spectrum disorders (FASD)**; Williams & Smith, 2015). Findings of FASD include atypical facial features (i.e., a thin upper lip and smooth surface rather than a vertical groove between the base of the nose and the border of the upper lip), microcephaly, short stature, attention and memory difficulties, executive function impairments, and cognitive impairments, including intellectual disability, speech and language difficulties, learning disabilities, and vision or hearing problems (Flak et al., 2014; Glass et al., 2017; Gross et al., 2017).

No amount of alcohol is considered safe during pregnancy. FASDs are entirely preventable developmental disorders. Despite this, in the United States 1 in 10 pregnant women reported alcohol use and 1 in 33 reported binge drinking in the past 30 days per data collected by the CDC from 2011–2013 using the Behavioral Risk Factor Surveillance System (Tan, Denny, Cheal, Snizek, & Kanny, 2015). A recent study looking at the worldwide prevalence of FASD reported a significantly high prevalence in South Africa, Croatia, and Italy (Roozen et al., 2016).

Prenatal alcohol exposure interferes with neuronal migration, brain organization, brain growth, and synaptic formation (Derauf, Kekatpure, Neyzi, Lester, & Kosofsky, 2009; Hendrickson et al., 2017; Jacobson et al., 2017; Jarmasz, Basalah, Chudley, & Del Bigio, 2017; Wozniak et al., 2017). Guidelines for evaluating and diagnosing FASD were recently revised and published by the American Academy of Pediatrics (Hagan et al., 2016; Hoyme et al., 2016).

Marijuana and Opioids

Statistics published from the National Survey of Drug Use and Health in 2014 indicated that 27 million people ages 12 or older had used an illicit drug in the past 30 days, equivalent to 10.2% of the U.S. population (CBHSQ, 2015). Common illicit drugs used include **marijuana** and hashish, nonmedical use of pain relievers and stimulants such as methamphetamines, tranquilizers, cocaine, heroin, inhalants, sedatives, and hallucinogens (LSD and Ecstasy). This section focuses on marijuana and opioids.

Marijuana policy is rapidly evolving in many states across the United States, with 30 states and the District of Columbia having laws broadly legalizing marijuana in some form at the time of the writing of this chapter.

Eight states and the District of Columbia have expansive laws legalizing marijuana for recreational use. Marijuana, often referred to as cannabis, is derived from the plant *Cannabis sativa*. It can be consumed in many forms, including smoking, vaping using e-cigarettes, hash oil, and edible products. The psychoactive properties of cannabis are due to the compound Δ -9-tetrahydrocannabinol (THC), which leads to both pleasurable and concerning effects, including relaxation, euphoria, heightened perception, sociability, sensation of time slowing, increased appetite, and decreased perception of pain, as well as paranoia, anxiety, irritability, impaired short-term memory, poor attention and judgement, and poor coordination and balance. Physiologic effects include tachycardia, hypertension, dry mouth and throat, and conjunctival injection (eye redness). There are also synthetic cannabinoids marketed as herbal mixtures and sold for recreational purposes under the names of Spice, K2, or Kronic.

Because of decriminalization and legalization of cannabis in certain states, the perception of marijuana being harmful has lessened, and, combined with the ease of access, rates of use have increased over the past several years. In 2015, 21% of youth reported using marijuana one or more times within the past 30 days (Kann et al., 2016). Marijuana readily crosses the placenta and is present in breast milk in pregnant and breastfeeding mothers (Baker et al., 2018; Grant, Petroff, Isoherranen, Stella, & Burbacher, 2018). Children born with prenatal exposure to marijuana are at increased risk for problems in the neonatal period, difficulty with emotional regulation after birth, and being a victim of domestic violence (Crume et al., 2018; Eiden, Schuetze, Shisler, & Huestis, 2018; Victor, Resko, Ryan, & Perron, 2018). Several studies have shown that long-term adolescent cannabis use may be associated with a decline in IQ (Hadland, Knight, & Harris, 2015), although a recent systematic review and metaanalysis did not find a strong correlation (Scott et al., 2018).

Recreational marijuana should not be confused with “medical marijuana” or cannabidiol, which does not have the psychoactive properties of THC and is being evaluated for the management of certain neurological conditions including refractory epilepsy, dystonia, spasticity, and central pain. While there are also trials underway for its use in developmental and behavioral conditions, including autism, ADHD, and anxiety disorders, there is no evidence to support its use for treatment of these conditions at this time.

Given the substantial increase in unintentional pediatric exposures, more commonly due to oral ingestions and subsequent hospital visits after recreational use of marijuana in certain states, several states have

passed regulations to prevent these exposures with requirements for warning labels, dosing regulations, packaging requirements, rules about edibles, and educational campaigns. As clinicians and health care providers, it is important to screen for marijuana exposure and its associated risk factors and to provide education that makes the point that decriminalization of marijuana does not necessarily mean it is safe.

Due to the rising opioid epidemic, children are at risk for prenatal and secondhand exposure to opioids. In several longitudinal studies, children born to mothers with opioid or polysubstance use during pregnancy had lower levels of cognitive functioning, lower birth weight, and decreased brain volumes compared to non-drug-exposed peers (Nygaard, Moe, Slinning, & Walhovd, 2015; Nygaard et al., 2018; Nygaard, Slinning, Moe, & Walhovd, 2017).

Pesticides

A **pesticide** is any substance or mixture of substances intended for preventing, destroying, repelling, or mitigating unwanted insects, plants, molds, and rodents. U.S. pesticide usage totaled more than 1.1 billion pounds in 2012, accounting for 20% of the pesticide usage in the world (Atwood & Paisley-Jones, 2017). Pesticides contain both active and inert ingredients, either of which can be toxic to human health. However, U.S. law currently does not require manufacturers to disclose the content and percentage of inert ingredients.

The most common source of pesticide exposure for children is in food, but pesticides are also present in the air, dust, soil, indoor and outdoor surfaces, and certain water sources. Pesticides can cross the placental barrier and be present in breast milk. Some of the major classes of pesticides include organophosphates, carbamates, pyrethroids, and organochlorines. Organochlorine pesticides such as dichlorodiphenyltrichloroethane (DDT), aldrin, dieldrin, and chlordane can remain in the environment for a very long time and tend to accumulate in the food chain. These pesticides are labelled *persistent toxic substances* and are banned for agricultural and domestic use in Europe, North America, and many countries in South America; however, DDT is still used to control malaria in some low-resource countries.

Organophosphate pesticides are widely used in agriculture yet are known to be neurotoxicants, especially for children. The risk to children is higher because the dose exposure is greater per kilogram of body weight and children have lower levels of enzymes to remove some of the organophosphates. High-dose

exposure to pesticides can lead to systemic health problems, including permanent damage to major organ systems and even death. Low-level chronic exposure is noted to have a multitude of adverse neurodevelopmental and health outcomes. Prenatal exposure to organophosphates has been associated with decreased IQ and social-emotional responsiveness, developmental delay, and autistic behaviors (Bouchard et al., 2011; Braun et al., 2014; Eskenazi et al., 2014; Eskenazi et al., 2008; Munoz-Quezada et al., 2013; Rowe et al., 2016; Shelton et al., 2014; Stein et al., 2016). Exposure to pesticides during childhood has been associated with cognitive impairments, ADHD, childhood cancers, and respiratory problems (Bouchard, Bellinger, Wright, & Weisskopf, 2010; Chen, Chang, Tao, & Lu, 2015; Raanan et al., 2015; Richardson et al., 2015; Wagner-Schuman et al., 2015).

The U.S. Environmental Protection Agency (EPA) regulates the pesticide use in food (i.e., grains, fruits, and vegetables) and sets standards for allowable pesticide residue in food under the Food Quality Protection Act. Under this provision, since 2007 the EPA has cancelled or restricted the use of several pesticides, including carbamates, several organophosphates, methyl parathion, and acephate.

Polychlorinated Biphenyls

PCBs are a group of industrial chemicals used in electronics, plasticizers, plastics, rubber products, pigments, dyes, carbonless copy paper, and pesticides. Manufacturing of PCBs was banned in the United States in 1979, but they are still present in products and materials produced before that time. They are released into the environment by improper disposal of hazardous waste or PCB-containing products, resulting in soil and water contamination. PCBs do not readily breakdown in the environment and can accumulate in the food chain due to their high lipid solubility. Fish are the most likely source of PCBs for humans. Farm-raised salmon may be high in PCBs and should be avoided by young children and women who are pregnant, nursing, or planning to become pregnant.

PCB ingestion has been associated with an increased risk of cancer, reduced immunity, decreased birth weight, and endocrine disruption. Low-level prenatal or postnatal exposure to PCBs has been associated with cognitive delays, behavior disorders, attention problems and impulsive behaviors, obesity, and autistic behaviors (Berghuis, Soechitram, Hitzert, Sauer, & Bos, 2013; Braun et al., 2014; Casas et al., 2015; Delvaux et al., 2014; Eubig, Aguiar, & Schantz, 2010; Tang-Peronard et al., 2014).

Endocrine Disruptors

Endocrine disruptors are chemicals that interfere with the function of the endocrine system. They can mimic, block, or alter the synthesis, metabolism, or excretion of hormones and thereby interfere with the action or concentration of hormones produced in the body. Under this umbrella, several chemicals have been noted to have endocrine-disrupting properties, including phthalates, PCBs, bisphenol A (BPA), DDT, perfluorinated compounds (PFCs), and organochlorine pesticides.

Bisphenol A is an industrial chemical used in the manufacturing of polycarbonate plastics. These plastics are used in metal food can linings, reusable water bottles, sports safety equipment, thermal paper receipts, and adhesives. Phthalates are a group of chemicals called plasticizers that are used to make plastics more flexible and harder to break. Both BPA and phthalates can leach out of products and be ingested. Exposure to phthalates and BPA can also occur through skin absorption, inhalation, and mouthing. Both BPA and phthalates can cross the placental barrier and influence the neurodevelopment of the fetus.

Exposure to endocrine disruptors at certain stages of brain and body development can have profound and lasting effects. Prenatal exposure to BPA in animal models has been shown to alter expression of genes coding for estrogen receptors and the dopamine transporter. BPA also disrupts signaling pathways in

lipid metabolism and alters serum gonadal hormones, leading to sex-specific effects on the developing fetus (Alyea & Watson, 2009; Ishido, Masuo, Terasaki, & Morita, 2011; Masuo & Ishido, 2011).

Prenatal and early childhood BPA exposure is associated with inattention, impulsivity, ADHD, disruptive behaviors, anxiety, and impairments in working memory (Braun et al., 2017; Evans et al., 2014; Perera et al., 2016; Tewar et al., 2016). Prenatal exposure to phthalates is associated with cognitive impairments, including lower IQ, inattention, hyperactivity, and poor social communication (Braun, 2017; Ejaredar, Nyanza, Ten Eycke, & Dewey, 2015). Oftentimes children are exposed to multiple endocrine disruptors simultaneously during sensitive periods of development, placing them at greater risk for significant impairments. Evidence-Based Practice Box 2.2 presents a discussion of endocrine-disrupting chemicals and neurodevelopment.

Congenital Infections

In addition to environmental toxicants, several biologic agents, including bacteria and viruses, have been identified to be teratogenic depending on the timing of exposure during pregnancy. Prenatal infections, commonly known as **TORCH**, which includes Toxoplasmosis, Other (i.e., syphilis, varicella-zoster, and parvovirus B19), Rubella, Cytomegalovirus, and

BOX 2.2 EVIDENCE-BASED PRACTICE

Endocrine-Disrupting Chemicals and Neurodevelopment

Endocrine-disrupting chemicals (EDCs) are a class of compounds that can increase the risk of disease throughout the lifespan by altering or interfering with the homeostasis of hormones or other signaling components of the endocrine system. Humans may be exposed to a mixture of EDCs simultaneously, and because the developing brain of the fetus and young child is more vulnerable to the effects of EDCs, this is of particular concern for this age group.

Braun (2017) has examined and summarized available epidemiological studies on the effects of early-life exposure to EDCs, particularly bisphenol A (BPA), phthalates, triclosan, and perfluoroalkyl substances (PFAS), on childhood neurobehavioral disorders and obesity. Review of available epidemiological studies shows that prenatal BPA and phthalate exposure is associated with adverse neurobehavioral outcomes, including ADHD, autism, cognitive deficits, and emotional problems but not the risk of obesity or being overweight. In contrast, prenatal PFAS exposure has been associated with low birth weight and increased risk of obesity or being overweight in children but not neurobehavioral deficits.

Application to Practice

- Clinicians should be aware of exposures to EDCs and their role in neurodevelopment.
- Clinicians can help identify and reduce exposure to BPA by promoting a balanced diet, the use of BPA-free plastics, reducing consumption of canned or packaged foods, and avoiding heating food in plastic containers to reduce leaching of BPA.

Herpes infections, account for 2%–3% of congenital anomalies. The American College of Obstetricians and Gynecologists recommends that pregnant women be screened for rubella and syphilis. However, universal screening for TORCH is not recommended due to the low yield and high costs.

More recently, the emergence of Zika virus (ZIKV) in the Americas and other regions has highlighted the importance of congenital infections in developmental disabilities. ZIKV is a vector-borne disease transmitted to humans directly (via sexual or mother-to-child transmission) or indirectly (via vector *Aedes aegypti* mosquitoes, blood transfusion, or organ transplantation). In 2015, there was a sharp increase in infants born with microcephaly noted 6 months after detection of ZIKV. The first outbreak of ZIKV was noted in 2016 in the continental United States. ZIKV infection in adults presents as a rash and fever that is generally mild and self-limited. However, vertical transmission of ZIKV to the fetus can lead to a broad spectrum of neurological impairments, growth restriction, and fetal loss. This collective presentation is termed as **congenital Zika syndrome (CZS)**. The fetuses and children diagnosed with CZS have been found to have microcephaly (a small head size), extra skin on the scalp, club feet, **arthrogryposis** (contractures of joints), increased muscle tone, spasticity, and hyperreflexia. Children with CZS are also noted to have atypical brain activity, seizures, and eye impairments leading to poor vision (da Silva Pone et al., 2018).

Follow-up studies of children with CZS show significantly delayed cognitive skills, motor skills, communication skills, and an increased incidence of cerebral palsy (Pessoa et al., 2018; Wheeler, 2018). The diagnosis of CZS is confirmed by blood or urine testing in the newborn period. Additional guidelines on evaluation and management of CZS are available through the CDC (Adebanjo et al., 2017). Currently, there is no vaccine available to prevent ZIKV infections. Management of a child with CZS involves an interdisciplinary and collaborative effort among obstetricians; neonatologists; pediatricians; neurologists; ophthalmologists; orthopedic surgeons; rehab specialists, including physical therapists, occupational therapists, and speech and language pathologists; early intervention services; social workers; and the educational system supporting the family of the child.

ENVIRONMENTAL TOXICANTS AND EPIGENETICS

Epigenetics is the study of heritable changes in gene expression that occur without changes in the DNA

sequence (see Chapter 1). Epigenetic changes can be described as a mechanism by which genes can be switched on or off by chemical signals, similar to a dimmer switch on a light. These epigenetic changes can alter the ways in which genes produce proteins and signal other genes; they can last for months to years but are potentially reversible. Environmental toxins can induce phenotypic changes using several epigenetic mechanisms (e.g., DNA methylation, histone modifications, and microRNA [miRNA] expression) and can change genome function. When epigenetic changes occur in a developing fetus, they can alter cellular function (Javed, Chen, Lin, & Liang, 2016).

For instance, prenatal exposure to tobacco via maternal smoking has been associated with changes in DNA methylation patterns in several genes. This could lead to a decreased number of neurons in the fetus and alterations in neurodevelopment (Armstrong et al., 2016; Banik et al., 2017; Chatterton et al., 2017). Fetal exposure to alcohol also has been associated with alteration in genes via multiple mechanisms, including DNA methylation, histone modification, alterations in miRNA expression, and alterations in several genes impacting neurodevelopment (Banik et al., 2017). In regions with high levels of arsenic in the ground water (contaminated naturally or from mining or agriculture), adults have been noted to have dose-dependent DNA hypermethylation in their blood DNA (Chanda et al., 2006; Pilsner et al., 2007), and prenatal arsenic exposure has been associated with global methylation of cord blood DNA in a sex-specific manner (Pilsner et al., 2012). Endocrine disruptors are also increasingly recognized for their epigenetic influences on neurodevelopment, thyroid regulation, reproduction capacity, and other metabolic processes (Derghal, Djelloul, Trouslard, & Mounien, 2016; Stel & Legler, 2015; Walker & Gore, 2017).

THE SOCIETAL COST OF ENVIRONMENTAL TOXICANTS

It is very challenging to estimate the societal cost associated with environmental exposures. It is most commonly measured as disability adjusted life years and monetary burden to the economy. The global economic burden attributed to cognitive impairments caused by lead exposure in the United States was estimated to be \$54 billion in the year 2010. For low- and middle-resource countries, the overall cost is estimated to be over \$1 trillion (Grandjean & Bellanger, 2017). Cognitive impairments associated with methylmercury, organophosphates, and polybrominated diphenyl ethers have been estimated to have resulted in

economic productivity losses in excess of \$314 billion in the year 2010. These costs do not account for other neurodevelopmental disorders such as ADHD and autism. Fetal alcohol spectrum disorders are another segment of preventable developmental disorders, with estimated costs of \$5.4 billion to the U.S. economy in the year 2003 (Popova, Stade, Bekmuradov, Lange, & Rehm, 2011).

PUBLIC POLICY IMPLICATIONS

The Toxic Substances Control Act (TSCA), passed in 1976 (PL 94-469), provided the EPA with the authority to require reporting, record keeping, testing requirements, and restrictions relating to chemical substances or mixtures. This law was amended and signed into law as the Frank R. Lautenberg Chemical Safety for the 21st Century Act (H.R.2576) in June 22, 2016. This new law prioritizes safety and risk evaluation of existing chemicals under the TSCA, and it requires affirmative findings on safety of any new chemical before it is introduced into the market (EPA, 2016). Although this is a step in the right direction, it will take some time for existing chemicals to be reviewed under the new law and for current guidelines to be updated reflecting available data on safety. It continues to be important to perform research and advocate for policy changes that are supportive of environmental chemical exposure prevention and management within the context of children's health and public health.

SUMMARY

- There are more than 1,000 chemicals identified as neurotoxicants based on human and animal studies.
- Chemical toxins have different effects on the human body depending on timing and dose exposure.
- Long-term neurodevelopmental adverse outcomes have been associated with *in utero* as well as postnatal exposure to multiple chemicals.
- Damage to the central nervous system (CNS) from environmental toxins can persist for years and is often irreversible.
- Mechanisms of action, such as epigenetic modifications, are being identified that can aid in the evaluation for safety of neurotoxicants.
- Because of the irreversible nature of damage observed in the CNS due to these environmental toxins, practitioners must focus on prevention of exposure.

CHAPTER 3

Birth Defects and Prenatal Diagnosis

Rhonda L. Schonberg and Margaret B. Menzel

Upon completion of this chapter, the reader will

- Become familiar with the process of genetic counseling and the genetic screening/testing options available to couples prior to and during pregnancy
- Understand the uses and limitations of noninvasive prenatal maternal blood screening for genetic syndromes and birth defects
- Become knowledgeable regarding the indications for and limitations of first- and second-trimester evaluation of birth defects using the techniques of ultrasonography, fetal magnetic resonance imaging, and echocardiography
- Be aware of the techniques for and possible results from amniocentesis and chorionic villus sampling and be able to determine when these diagnostic tests may be indicated
- Understand the benefits of a multidisciplinary team in a comprehensive prenatal diagnosis center or fetal center for the counseling, evaluation, and management of fetal anomalies when they are identified
- Become familiar with alternative reproductive technology (ART), including *in vitro* fertilization with preimplantation genetic diagnosis, and understand under what circumstances couples might benefit from such technologies
- Understand the psychosocial issues and needs of families who are at increased risk for having children with genetic disorders or birth defects

The prenatal diagnosis of a child with a developmental disability or a genetic disorder has a major impact on parents, siblings, and extended family members. As parents come to terms with their child's disability or disorder, they may try to understand what happened and why. Although most infants in the United States are born without complications, 3% of all births, 1 in every 33 infants, is born with a birth defect or genetic

disorder (Centers for Disease Control and Prevention, 2017). These events can affect any pregnant woman regardless of age, socioeconomic status, or ethnicity. Although medical professionals recognize certain circumstances that increase the risk of having a child with a birth defect (a number of which are discussed in this chapter), it must be acknowledged that most affected newborns will be born to couples who were unaware

of any risk and had no family history of similarly affected children. When this occurs, genetic evaluation (discussed in Chapter 1) may help determine a diagnosis and mode of inheritance. Advances in prenatal screening and diagnosis have provided couples with the opportunity to gain detailed information about their fetus (e.g., the presence of, or increased risk for, a birth defect or genetic disorder) and examine a range of family planning options. This chapter discusses 1) genetic screening that is available prior to and during pregnancy, 2) diagnostic testing appropriate for fetuses who have been determined to be at an increased risk for a specific genetic disorder, and 3) alternative reproductive choices.

■ ■ ■ CASE STUDY

Jennifer, a 32-year-old experiencing her first pregnancy, opted for cell-free DNA noninvasive prenatal testing (DNA/NIPT) at 10 weeks' gestation because she had been told she could learn the gender of her fetus. The results were unexpected; instead of an XX (female) or XY (male) pattern, the fetus had findings consistent with a single sex chromosome XO (Turner syndrome, see Appendix B). Jennifer met with a genetic counselor who clarified that DNA/NIPT was a screening rather than a diagnostic test and had certain limitations to its accuracy, especially in detecting sex chromosome abnormalities. The genetic counselor reviewed further diagnostic testing options, including chorionic villus sampling (CVS) and amniocentesis. Jennifer declined further genetic testing at that time but agreed to have follow-up ultrasounds and fetal echocardiography given the increased risk for a congenital heart defect (CHD) in children with Turner syndrome. At her 12-week ultrasound, the **nuchal translucency measurement** (a measure of the collection of fluid under the skin at the back of the fetal neck) was increased, and a fetal echocardiogram at 20 weeks' gestation indicated a CHD—coarctation of the aorta. Both of these findings were consistent with a diagnosis of Turner syndrome. Jennifer then opted for amniocentesis, which confirmed the diagnosis.

This diagnosis allowed Jennifer and her husband time to prepare for the birth of a child with Turner syndrome. They met with a pediatric geneticist, and Jennifer was followed closely with fetal echocardiograms by a pediatric cardiologist as well. A plan for immediate postnatal evaluation of Jennifer's infant by cardiology/cardiovascular surgery and genetics personnel was put into place. She and her husband were connected with the Turner Syndrome Society and two other families who had come through the fetal medicine center and subsequently had children with Turner syndrome. Although learning about the diagnosis was initially difficult for

Jennifer and her family, she felt empowered by the information she received and the plan she and her husband had in place for after the infant was born. Ultimately, Jennifer felt that learning about the diagnosis prenatally allowed her family time to digest the information and plan and prepare for the follow-up needed after delivery.

At birth, a cardiac evaluation determined that Jennifer's infant, Hope, had a critical CHD that required immediate surgery. The coarctation was successfully repaired by the cardiovascular surgeon and Hope, now 8 years old, is doing very well. She has typical features of Turner syndrome, such as being small and having a mild learning disability, but she is a happy and well-adjusted child. Hope will face other challenges as she gets older, but her mother has become an expert and advocate for Turner syndrome, and she is confident that Hope will have a happy and productive life.

Thought Questions:

How can the prenatal (versus postnatal) diagnosis of a birth defect or genetic syndrome be helpful for a family? Can you think of reasons why patient advocacy groups may be in favor of, or against, prenatal screening and diagnosis? Why might a fertile couple consider assisted reproductive technologies to have a child?

GENETIC ASSESSMENT AND CARRIER DETECTION

Assessing reproductive risk involves reviewing an individual's medical and pregnancy history and taking an extended family history. This includes obtaining information about the presence of birth defects, genetic disorders, unexplained infant deaths, and recurrent pregnancy losses. Information about maternal medication use and occupational or other exposures, including infections such as CMV, toxoplasmosis, or Zika virus, can also provide clues to possible reproductive risks (see Chapter 2).

As of 2017, more than 24,000 genetic disorders have been identified (National Center for Biotechnology Information, 2017). Specific genetic testing is clinically available for over 5,000 of these disorders, and the number continues to grow (National Center for Biotechnology Information, n.d.). Information about these genetic disorders is available to the lay public through 1) the Genetics Home Reference, a National Library of Medicine–supported database (<http://ghr.nlm.nih.gov>); 2) the Genetic Alliance, a clearinghouse for information and support groups for genetic disorders (<http://www.geneticalliance.org>); and 3) the National Organization for Rare Disorders (<http://www.rarediseases.org>).

Knowing an individual's ethnic background can be one of the initial steps in assessing reproductive risk. Individuals from certain ethnic backgrounds (e.g., Ashkenazi Jewish and Amish) have a higher risk of carrying specific gene mutations that are known to be associated with particular genetic disorders (see Table 3.1). In addition, the American College of Obstetrics and Gynecology (ACOG) recommends that all women who are pregnant or are considering pregnancy should have carrier screening for spinal muscular atrophy (SMA), Fragile X syndrome, hemoglobinopathies, and cystic fibrosis (ACOG, 2017a). SMA, most hemoglobinopathies, and cystic fibrosis are autosomal recessive disorders. Fragile X syndrome is X-linked. For recessive disorders, both parents must be carriers of a mutation in the same gene for there to be an increased risk of having an affected child (see Chapter 1). For Fragile X syndrome, the carrier state in the mother alone is sufficient to increase the risk to the fetus and can have health implications for the carrier mother as well (Wheeler et al., 2014). Advanced knowledge of risk provides couples with the opportunity to consider alternative reproductive options or to undergo prenatal diagnostic testing.

The cost of DNA analysis and sequencing has decreased precipitously since the mid-2000s.

This, along with other advancing technologies, has prompted the development of expanded carrier screening wherein laboratories can offer screening panels of up to 100 or more conditions at a relatively low cost. Many obstetrics-gynecology and maternal fetal medicine practices are now offering this expanded carrier screening to couples of all ethnicities prior to or early in pregnancy. Although there are clear benefits of carrier screening, there are also limitations, such as different detection rates among disorders and residual risks based on an individual's ethnicity.

If an individual is found to be a carrier for a change in a gene associated with a particular condition, it is important that they meet with a genetic counselor. The woman can then learn about the clinical presentation of the disorder as well as the incidence, penetrance, and variability in expression so that she can decide whether to pursue additional testing in her partner and/or fetus (Grody et al., 2013).

A couple also may be at increased risk for having a child with a genetic disorder if a previous child or other close family member has been diagnosed with the disorder. In these situations, a detailed review of the family history, pregnancy history, and medical records is performed along with examination of the

Table 3.1. Disorders with increased carrier frequencies in particular ethnic groups

Ethnic group	Disorder at risk	Estimated carrier frequency
European and North American (Caucasian)	Cystic fibrosis	1 in 25
Ashkenazi Jewish (Eastern European Jewish)	Tay-Sachs disease	1 in 27
	Canavan disease	1 in 40
	Cystic fibrosis	1 in 25
	Gaucher disease (type 1)	1 in 15
	Bloom syndrome	1 in 100
	Niemann-Pick disease (type A)	1 in 90
	Fanconi anemia	1 in 90
	Glycogen storage disease (type 1A)	1 in 71
	Maple syrup urine disease (MSUD)	1 in 81
	Mucopolidosis IV (ML IV)	1 in 125
	Familial dysautonomia	1 in 36
African American or Western African	Sickle cell anemia	1 in 12
	Beta thalassemia	1 in 50
	Cystic fibrosis	1 in 61
Mediterranean	Beta thalassemia	1 in 15 to 1 in 20
Asian	Alpha thalassemia	1 in 8 to 1 in 20
French Canadian	Tay-Sachs disease	1 in 27
Southeast Asian	Beta thalassemia	1 in 4 to 1 in 150

This table was published in *Medical complications during pregnancy* (5th ed.), B.N. Burrow & T.P. Duffy, in the chapter Clinical Genetics, by Seashore, M.R., p. 216. Copyright W.B. Saunders, 1999; adapted by permission.

affected individual by a pediatric geneticist to verify or establish the diagnosis. This process is necessary in order to discuss reproductive risks and prenatal testing options for future pregnancies. See Box 3.1 to learn about the role of the genetic counselor in this process.

SCREENING TESTS DURING PREGNANCY

First- and second-trimester screening can modify the risk assessment for having a child with Down syndrome, trisomy 18, trisomy 13, a sex chromosome abnormality, and certain microdeletion syndromes. While the chance of having a child with a chromosomal abnormality increases with maternal age (Hook, 1981; Morris, Wald, Mutton, & Alberman, 2003; see Figure 3.1), the vast majority of pregnancies, and therefore most newborns with Down syndrome, are born to younger women. As a result, ACOG has recommended that prenatal screening and diagnostic testing be offered to all women, regardless of age (ACOG, 2017a); this is now considered the standard of care. The following sections describe the options for prenatal testing during the first and second trimesters.

Figure 3.1. Risk of trisomy 21 and all chromosome abnormalities in pregnant women of various ages. Risk increases markedly after 35 years of age. (Source: Hook, 1981.)

First-Trimester Screening

Screening for **aneuploidy** (an abnormal number of chromosomes) and birth defects during the first trimester of pregnancy allows for earlier assessment, diagnosis, genetic counseling, and discussion of follow-up

BOX 3.1 INTERDISCIPLINARY CARE

The Genetic Counselor

Throughout the United States, many medical centers employ a genetic counselor (<http://www.nsgc.org>) to assist with this genetic assessment. The value of having a genetic counselor evaluate the patient and be a member of the multidisciplinary medical team is well documented (Lawrence, Menzel, & Bulas, 2016). With the rapid expansion of complex genetic screening and testing options, the importance of genetic counselors has only grown.

Genetic counselors are medical professionals with a master's degree in genetic counseling and board certification/eligibility through the American Board of Genetic Counseling (ABGC). They have specialized training and expertise in evaluating risks for genetic disease and communicating complex information to families and other health care providers in the prenatal, pediatric, oncology, or laboratory setting.

Meeting with a genetic counselor prior to or during pregnancy allows couples the time to review specific questions about their own pregnancy and family or medical history, as well as questions regarding prenatal screening and diagnostic options.

Genetic counselors can identify and provide resources such as support groups, counseling, patient-appropriate literature, and other family connections to patients. They help other members of a multidisciplinary prenatal team by sharing information with referring providers and communicating the following:

- Patient medical and family history
- The indication for referral
- Prior ultrasounds and genetic screening/testing results
- Guidance regarding patient expectations
- Follow-up on diagnoses

testing. Such screening includes ultrasonography, maternal serum (blood) screening, and DNA/NIPT. ACOG recommends that all women over 35 years old be offered both screening and diagnostic testing for chromosome abnormalities using CVS performed in the first trimester or **amniocentesis** performed in the second trimester (ACOG, 2016a; Wilson et al., 2013).

First-Trimester Ultrasound An early ultrasound can establish fetal viability, determine the number of fetuses (especially useful in cases involving assisted reproductive technology), suggest certain genetic/chromosomal disorders and birth defects (e.g., Down syndrome, CHDs, and meningomyelocele), and confirm gestational dating and placental positioning (Table 3.2). Fetal structural anomalies are found in up to 3% of all pregnancies, and approximately half of all major anomalies can be detected with a first-trimester ultrasound (Edwards & Hui, 2018). The highest detection rate with ultrasound at 11–14 weeks was for neck anomalies (92%), whereas limb (34%), face (34%), and genitourinary anomalies (34%) were associated with the lowest detection rate (Rossi & Perfumo, 2013). Increased nuchal translucency seen on an ultrasound, even in the absence of a chromosomal abnormality, is associated with adverse outcomes, including a greater incidence of CHD, other fetal anomalies, genetic syndromes (e.g., Turner syndrome), and

fetal death (Sonek & Nicolaides, 2010). Given the association with CHD, a fetal echocardiogram is often recommended in these situations.

For women of advanced maternal age, early ultrasound can impact further testing strategies and clinical management. In one study, 16% of women over age 35 who had considered having cell-free fetal DNA screening altered their decision and care plan based on an abnormal first-trimester ultrasound finding. Some decided to have further diagnostic testing (i.e., amniocentesis or CVS) instead of screening, while others chose to end their pregnancy (Vora, Robinson, Hardesty, & Stamilo, 2017). First-trimester ultrasound is also most accurate for gestational dating. This is important for maternal serum screening for aneuploidy, which can be drawn as early as 9 weeks.

First-Trimester Maternal Serum Screening

Testing of maternal serum-free **human chorionic gonadotropin (hCG)** and pregnancy-associated plasma protein A (PAPP-A) at 9–14 weeks' gestation, when used in combination with a first-trimester nuchal translucency ultrasound at 11–13 weeks, further contributes to the risk assessment. This combined screening has been found to correctly identify 90%–95% of fetuses with Down syndrome and trisomy 18 and 13, and it has less than a 5% false-positive rate (Anderson & Brown, 2009; Nicolaides, 2004). In addition to identifying these chromosomal abnormalities, levels of maternal, serum-free β -hCG or PAPP-A that are less than the 5th percentile or greater than the 95th percentile can indicate an adverse pregnancy outcome, specifically an increased risk for preeclampsia and/or intrauterine growth retardation, both of which warrant additional monitoring.

Fetal Echocardiogram A first-trimester fetal echocardiogram (ECHO) is useful for evaluating fetuses with an increased risk for congenital heart disease. Indications include 1) increased nuchal translucency, 2) a first-degree affected relative, 3) a known or suspected chromosome abnormality associated with CHD, 4) an extra cardiac abnormality, or 5) exposure to certain teratogens. Fetal ECHO permits the evaluation of the structure and function of the fetal heart and monitors fetal blood flow. Although it can be performed as early as 11 weeks' gestation in a high-risk fetus, the ECHO should be repeated at 18–20 weeks, when it is most accurate (Rayburn, Jolley, & Simpson, 2015). The presence of prenatally identified CHD can affect *in utero* management, delivery options, and neonatal intervention or follow up (Donofrio et al., 2014).

Table 3.2. Ultrasound findings in certain chromosomal abnormalities

Syndrome	Findings
Trisomy 13	Cleft lip and palate
	Congenital heart defect
	Cystic kidneys
	Polydactyly
	Midline facial defect
	Brain abnormalities (holoprosencephaly)
Trisomy 18	Clenched hands with overlapping fingers
	Congenital heart defect
	Polyhydramnios
	Growth retardation
	Rocker-bottom feet
Trisomy 21	Omphalocele
	Gastrointestinal malformations (duodenal atresia)
	Congenital heart defect
	Excess neck skin/increased nuchal translucency
	Absent nasal bone

Sources: D'Alton and DeCherney (1993); Nicolaides (2004); and Viora et al. (2005).

Cell-Free DNA/NIPT Screening Over the past decade, the landscape for prenatal screening has changed significantly with the advent of NIPT, also known as cell-free fetal DNA screening. During pregnancy, fetal DNA fragments from both the fetus and pregnant woman are present in the maternal bloodstream (Figure 3.2; Benn, Cuckle, & Pergament, 2013). Cell-free fetal DNA fragments, mostly of trophoblast origin, cross the placenta, enter the maternal circulation, and are cleared within hours. Fetal DNA detected during a pregnancy represents DNA from the current gestation. For women at increased risk for aneuploidy, the American College of Medical Genetics and Genomics (ACMG) suggests that maternal serum cell-free fetal DNA screening should be considered as a primary screening tool. NIPT is routinely available as a screen for trisomy 21, 18, and 13, with most laboratories quoting detection rates of 99% for trisomy 21 and 95% for trisomy 18 or 13. NIPT screening has recently expanded in scope, and many laboratories now include sex chromosome abnormalities and some microdeletion syndromes in their panels, although the **positive predictive value** (the proportion of positive results that correctly predicts the disorder being screened) is significantly lower.

Advantages of NIPT include 1) being done as early as 9 weeks in pregnancy and reliable throughout the remainder of pregnancy; 2) having a higher detection rate and lower false-positive rate than any of the other first- or second-trimester screens for Down syndrome, trisomy 18, and trisomy 13; and 3) being able to screen for other genetic abnormalities such as triploidy, sex chromosome abnormalities, and some micro deletion syndromes. It is important to remember, however,

Figure 3.2. Cell-free fetal DNA enters maternal circulation through the placenta. Approximately 10% of DNA in maternal plasma is fetal. This allows testing for increased presence of DNA associated with certain chromosomes. It may also identify some microduplication or microdeletion syndromes in the fetus.

that NIPT is a screening, not a diagnostic tool like CVS or amniocentesis, and it has significant limitations. Approximately 0.5%–1% of women will receive an inconclusive test result due to an insufficient fetal fraction of free DNA, and mosaicism, partial trisomies, unbalanced translocations, and single-gene disorders cannot routinely be identified by NIPT (Cuckle, Benn, & Pergament, 2015). In addition, NIPT has not been validated in triplet or higher multiple pregnancies or in pregnancies conceived using egg donation. Also, unlike first- and second-trimester serum screening, NIPT does not detect maternal serum abnormalities that may indicate additional pregnancy or fetal complications, such as an increased risk for preeclampsia, intrauterine growth retardation, or other fetal abnormalities (Beulen et al., 2017).

Although the sensitivity and specificity of NIPT in the low-risk population (women under 35 years of age at delivery) seems to be similar to that in the high-risk population, the positive predictive value is lower in the low-risk population given the lower prevalence of abnormalities (ACOG, 2015). Thus, the recommendation by ACOG continues to be that first-trimester maternal serum and ultrasound screening remains the first-line screen offered to the low-risk general obstetric population.

Chorionic Villus Sampling CVS involves obtaining a small biopsy of the **chorion**, the outermost membrane surrounding the embryo. Chorionic **villi**, consisting of rapidly dividing cells of fetal origin, can be analyzed directly or grown in culture prior to testing (Blakemore, 1988). CVS can be used for chromosome analysis, enzyme assay (for inborn errors of metabolism; see Chapter 16), molecular DNA analysis (identifying specific mutations that cause genetic diseases), and chromosome microarray analysis. It is not, however, diagnostic for neural tube defects, such as spina bifida, so a maternal serum α -fetoprotein (AFP) screen at 16+ weeks is recommended after a CVS.

CVS is performed at approximately 10–12 weeks' gestation, usually before a woman appears to be pregnant and prior to **quickening** (the detection of fetal movement by the mother). Using ultrasound guidance, a chorionic villus biopsy is performed either by suction through a small catheter passed into the cervix or by aspiration via a needle inserted through the abdominal wall and uterus (Figure 3.3). CVS is considered the safest invasive prenatal diagnostic procedure prior to the 14th week of gestation. There is a less than 1% risk of procedure-related pregnancy loss and, provided CVS is performed after 10 weeks' gestation, there is no increased risk of causing a fetal anomaly (Ogilvie & Akolekar, 2014).

Figure 3.3. CVS is performed at 10–12 weeks' gestation. It can be transcervical or transabdominal. Guided by ultrasound, a catheter is inserted through the vagina and passed into the uterus, or a needle is inserted through the abdomen into the uterus. A small amount of chorionic tissue is removed by suction. The tissue is then examined under a microscope to make sure it is sufficient and sent to the lab. Karyotype, microarray, enzyme, and/or DNA analyses can be performed. Cell culture is needed for most analyses. Results are available in a few days in select situations; more often they are ready in 10–14 days.

Second-Trimester Screening

Maternal serum screening and ultrasonography are also offered in the second trimester. In addition, magnetic resonance imaging (MRI) and fetal echocardiography can add important information in select circumstances at this point in the pregnancy.

Second-Trimester Maternal Serum Screening

Because not all women present for prenatal care in the first trimester, second-trimester screening remains useful (Shamshirsaz, Benn, & Egan, 2010). Approximately 70% of pregnant women in the United States have a maternal serum screen and/or a detailed ultrasound study performed in the second trimester to screen for chromosome abnormalities, birth defects, or inadequate fetal growth.

For the quadruple (Quad) screen, a maternal blood specimen can be drawn at approximately 16 weeks' gestation and analyzed for 1) AFP, 2) β -hCG, 3) unconjugated serum estriol, and 4) inhibin A. In combination with first-trimester screening results, this screening can increase the detection rate for Down syndrome to about 95%, with a 5% false-positive rate (Anderson & Brown, 2009; Malone et al., 2005). These serum markers, combined with other indicators, including maternal age, weight, race, diabetes status, and number of fetuses, can also be used to assess the risk for neural tube defects (**spina bifida** and **anencephaly**), abdominal

wall defects (**gastroschisis** and **omphalocele**), and trisomy 18 syndrome (see Appendix B). If the quad screen in the second trimester suggests an increased risk for a fetal abnormality, diagnostic testing by amniocentesis and a detailed ultrasound evaluation should be considered. It should be noted that correct gestational age assessment is essential for an accurate interpretation of all maternal serum screening results.

Second-Trimester Ultrasonography Approximately two-thirds of pregnant women undergo second-trimester **real-time ultrasonography**. Prenatal ultrasound studies at 18–22 weeks' gestation can identify more than 70% of major structural anomalies in fetuses. Once an abnormality is suspected, other imaging, such as a fetal echocardiogram or fetal MRI, may be suggested to further delineate the diagnosis and contribute to management (Edwards & Hui, 2018). Common anomalies detected by ultrasound imaging include neural tube defects, abdominal wall defects, facial clefts, renal anomalies, skeletal anomalies, brain anomalies, and CHD. Although the identification of structural abnormalities by ultrasound is improving, it does not replace definitive diagnostic testing for chromosomal abnormalities, micro duplication or deletion syndromes, genetic mutations, and biochemical analyses that are possible using amniocentesis or CVS. In most cases, ultrasound and other diagnostic testing complement each other in making a diagnosis.

Amniocentesis Amniocentesis is traditionally performed between 15 and 20 weeks' gestation, although it can be performed beyond 20 weeks in select situations. The procedure is done under ultrasound guidance in a sterile field. A needle is inserted just below the mother's umbilicus and through the abdominal and uterine walls. Once in the amniotic sac, 1 to 2 ounces of amniotic fluid are aspirated (Figure 3.4). Through natural processes, mostly fetal urination, the aspirated fluid is replenished within 24 hours. The risk of pregnancy loss following a genetic amniocentesis at 15+ weeks is approximately 0.5%. The specific loss risk is dependent on the provider performing the procedure and possible other maternal complications (Carlson & Vora, 2017; Ogilvie & Akolekar, 2014). Amniocentesis performed before 14 weeks' gestation has been associated with an increased risk of pregnancy loss, a higher incidence of musculoskeletal deformities (most often clubfoot), and a greater chance of amniotic fluid leakage. For this reason, CVS rather than amniocentesis continues to be the preferred procedure for first-trimester diagnosis (Wapner, 2005).

Figure 3.4. Amniocentesis. Approximately 1 to 2 ounces of amniotic fluid are removed at 16–20 weeks' gestation. The sample is spun in a centrifuge to separate the fluid from the fetal cells. The alpha-fetoprotein in the fluid is measured to screen for a neural tube or abdominal wall defect. The fluid can also be used to check for metabolites associated with inborn errors of metabolism when indicated. The cells are grown for a week, and then a karyotype, microarray, enzyme, or DNA analysis can be performed. Most results are available in 10–14 days. (Source: Rose & Mennuti, 1993.)

One advantage of amniocentesis over CVS or maternal serum screening is the ability to assay the amniotic fluid directly for abnormal levels of biochemical compounds, such as AFP for neural tube and some abdominal wall defects. Ultrasound evaluations cannot detect all cases of neural tube defects; however, when combined with an elevated amniotic fluid AFP level and a positive **acetylcholinesterase** test, an abnormal ultrasound identifies virtually all neural tube defects (Rose & Mennuti, 1993). The diagnosis of fetal infections such as CMV or toxoplasmosis is also most accurate using amniotic fluid rather than maternal serum.

MRI In selected instances, fetal MRI can add to the clinical understanding of an ultrasound variation when used at 17 weeks' gestation or later (Bulas, 2007; Reddy, Filly, & Copel, 2008). Because MRI uses ultrafast imaging sequences, neither the mother nor fetus requires sedation, and there are no other known maternal or fetal risks with its use. First-trimester evaluation of the fetus by MRI, however, is avoided because of limited resolution of fetal structures.

MRI is particularly useful in conjunction with ultrasound for evaluation of the fetal brain (Rossi & Perfumo, 2014). Among other structures, fetal brain MRI can demonstrate the presence (Figure 3.5A) or absence (Figure 3.5B) of the **corpus callosum** (the band of tissue connecting the two cerebral hemispheres), **Chiari malformations** (the downward displacement of the cerebellum through the opening at the base of the skull, seen most commonly in spina bifida), and **hydrocephalus** (significantly enlarged ventricles) (Glenn & Berkovich, 2006). MRI also is useful in the evaluation of the airway, for the identification of lung lesions, and complex abdominal pathology. It is particularly

Figure 3.5. A) MRI images of a fetal brain with a corpus callosum. B) MRI images of a fetal brain with agenesis of the corpus callosum. (Courtesy of Dorothy I. Bulas, MD, Department of Diagnostic Imaging, Children's National Medical Center, Washington, DC)

beneficial when there is low or no amniotic fluid surrounding the fetus, as ultrasound imaging is limited in this situation.

Fetal Echocardiography The field of fetal cardiac medicine focuses on the diagnosis of CHD, assessment of cardiac function and the cardiovascular system, and evaluation of treatment options (Donofrio et al., 2014). CHD is the most common birth defect in children (occurring in 8.3 out of 1,000 children, or 0.8% of the population) and represents more than one-third of all deaths from birth defects (Marelli et al., 2014; Reddy et al., 2008). Fetal echocardiography is the best tool in the assessment of a fetus with CHD. This targeted ultrasound is ideally performed at 18–22 weeks' gestation, when the fetal heart is approximately the size of an adult's thumbnail. A family history of CHD, an increased nuchal translucency in the first trimester (Souka et al., 2005), maternal diabetes or lupus, a fetal diagnosis of Down syndrome or velocardiofacial syndrome (see Appendix B), or other birth defects noted by ultrasound all increase the likelihood that a CHD will be identified.

When a CHD is identified *in utero*, a detailed ultrasound study is indicated to screen for other malformations. Approximately 10%–15% of infants with CHD have an underlying chromosomal abnormality and will often have additional anomalies and intellectual disability (Table 3.2; Brown, 2000). Infants with isolated critical CHD are also at risk for developmental delay or cognitive impairments as a result of hypoxemia and morbidity from corrective cardiovascular surgery.

When a fetus is identified with a CHD, genetic counseling and diagnostic testing via amniocentesis are warranted because the long-term outcome for a child with an isolated CHD can be much different than for a child with CHD as part of a chromosomal or genetic syndrome.

Because the fetal circulation differs from that of the newborn, not all CHDs can be identified prenatally; therefore, a careful cardiac evaluation should also be performed in the newborn period for infants known to be at increased risk. Early diagnosis and management is important in planning for prenatal or postnatal intervention and may play a role in improving the neurocognitive outcome. See Box 3.2 for more on genetic testing and fetal CHD.

Diagnostic Testing of Fetal Cells Both CVS and amniocentesis are well-established techniques for obtaining fetal cells. The most common testing requested is chromosomal analysis (karyotype) and/or microarray. When indicated, biochemical analysis for inborn errors of metabolism or DNA analysis for disorders such as fragile X syndrome or cystic fibrosis can also be performed (Thompson, McInnes, & Willard, 2004). Indeed, any genetic disorder for which a familial DNA mutation has been identified can be assessed using DNA isolated from the fetal cells. Studies other than microarray and/or chromosome analysis are generally only considered when a pregnancy is thought to be at increased risk for a particular condition.

ACOG guidelines updated in 2016 recommend chromosomal microarray (CMA) as the first tier of

BOX 3.2 EVIDENCE-BASED PRACTICE

Genetic Testing and Fetal Congenital Heart Disease

Approximately 15% of fetuses with congenital heart disease (CHD) have a chromosome abnormality. Thus, all patients with a fetal diagnosis of CHD should be offered genetic counseling and prenatal diagnosis. The American College of Obstetrics and Gynecologists and Society for Maternal-Fetal Medicine now recommend offering chromosomal microarray analysis (versus karyotype alone) for those pursuing prenatal diagnosis when there are one or more structural abnormalities.

Regarding CHD specifically, the single nucleotide polymorphism microarray increases the likelihood of identifying clinically significant chromosomal differences that aren't detectable by karyotype. One study looking at the detection of microarray abnormalities in prenatal CHD found that 19.8% of fetuses with a CHD had an array abnormality (17.4% in isolated CHD and 25% in syndromic cases). When karyotype alone was performed, 14% of fetuses had a chromosomal abnormality (Turan et al., 2018; Mademont-Soler et al., 2013).

The take away message is the following:

- Genetic counseling is important for all patients with a prenatal diagnosis of CHD.
- Chromosomal microarray should be offered in lieu of, or in addition to, a normal karyotype for patients with a fetal diagnosis of CHD.

testing in the case of an ultrasound finding of a fetal structural anomaly, with the caveat that if the abnormality is strongly suggestive of a particular aneuploidy, a karyotype (chromosomal analysis) may be offered before CMA. In a prospective study by Wapner et al. (2012) evaluating fetuses with normal karyotype by amniocentesis or CVS, microarray analysis identified clinically relevant deletions or duplications in 6% of fetuses with a structural abnormality and 1.7% of those whose indication for prenatal diagnosis was advanced maternal age or abnormal screening results.

GENETIC COUNSELING AND DECISION MAKING

When a concern for a congenital abnormality is raised, prenatal testing offers parents the opportunity of learning more about the condition and making an informed decision on how to proceed. Some parents make the incredibly difficult and painful choice to terminate the pregnancy. For those who continue the pregnancy, there is time to learn more about the disorder prior to delivery, enabling the family to start preparing emotionally and logistically for the birth of a child who may require extensive supports. Prenatal testing ensures that if immediate postnatal surgical or other medical intervention is required, the family and medical team have time to develop a treatment plan. It may also provide the time to arrange for palliative care for a child who may not survive for very long after birth because of the severity of the anatomical abnormalities. Perinatal palliative care is a valuable option for families who choose to continue a pregnancy with a fetus where early postnatal death is likely. Clinicians specifically trained in palliative care can provide resources and support to help families make the most of the precious time they have with their child both inside and/or outside the womb. Resources for both patients and health care providers can be found at www.perinatalhospice.org.

Due to the complexity of prenatal testing and screening (see Figure 3.6), it is becoming more challenging for parents to process their options and make informed decisions; therefore, it is increasingly important for them to receive genetic counseling. As technology advances, the indications for prenatal diagnosis will continue to increase and detection will continue to improve; however, even the most sophisticated prenatal diagnostic technology cannot guarantee the birth of a “typical” child. Many of the disorders that cause developmental disabilities in the absence of structural malformations are not currently amenable to prenatal diagnosis unless there is a known familial genetic diagnosis.

DECREASING THE RISK OF A BIRTH DEFECT

Attention to certain environmental exposures during pregnancy can help decrease the risk for some birth defects. Recommendations include receiving early prenatal care, avoiding alcoholic beverages and tobacco, and minimizing unnecessary medications. In addition, pregnant women should try to avoid exposure to infection, excess vitamin A (e.g., Accutane for acne), and frequent consumption of fish that are known to have elevated mercury content (e.g., mackerel, marlin, orange roughy, swordfish, tilefish, and ahi tuna; ACOG, 2017b). Daily ingestion of 0.4 mg of folic acid (found in most multivitamins) by all women of childbearing age starting 3 months before attempted conception and continuing through the first trimester is recommended to reduce the risk of neural tube defects.

If not treated appropriately, a number of maternal conditions can also predispose an infant to birth defects or developmental delay. A woman with phenylketonuria is at risk of having a child with microcephaly and intellectual disability if she does not maintain a phenylalanine-restricted diet during pregnancy (see Chapter 16). If not under good control, chronic maternal disorders, including diabetes and lupus, increase the risk for congenital anomalies to the fetus. Certain medications taken to control illness, such as anti-epileptic drugs, can also increase the risk for birth defects. Ideally, the risks versus benefits of chronic medication use during pregnancy should be discussed by the patient and her care provider prior to conception.

ALTERNATIVE REPRODUCTIVE CHOICES

When a couple is at increased risk to have a child with a serious genetic disorder, reproductive options are available to minimize that risk utilizing **assisted reproductive technology** (ART). Given its complexities, genetic counseling is recommended prior to initiating ART.

Preimplantation Genetic Diagnosis

Preimplantation genetic diagnosis (PGD) is available for couples who 1) are at risk of having a child with a known genetic disorder, 2) wish to conceive an unaffected child that is biologically their own, and 3) want to avoid having to consider pregnancy termination. Originally introduced in 1990 for couples at risk of having a child with an X-linked disorder, PGD accuracy continues to improve with the use of next-generation sequencing (NGS) analysis to identify DNA sequence differences (i.e., single-gene mutations) (Dolan, Goldwaser, & Jindal, 2017; Stern, 2014).

Figure 3.6. This American College of Obstetrics and Gynecology (ACOG) overview of prenatal testing includes the screening and diagnostic options available through pregnancy. (Reprinted with permission from American College of Obstetricians and Gynecologists. Prenatal genetic testing chart [infographic]. Washington, DC; American College of Obstetricians and Gynecologists; 2016. Available here: <https://www.acog.org/Patients/FAQs/Prenatal-Genetic-Testing-Chart-Infographic>. Retrieved December 12, 2017.)

There are two approaches to PGD, as illustrated in Figure 3.7. Both include the methods of *in vitro fertilization* (IVF). IVF is accomplished by harvesting a woman's egg cells and fertilizing them outside the womb with the father's sperm. The first involves **polar body testing** of the woman's eggs to establish the presence or absence of the mutation in question (e.g., looking for the Tay-Sachs gene mutations in a couple who are both carriers of this disorder). Only embryos from fertilized eggs determined to contain the normal gene(s)

are then transferred to the mother's uterus to establish a pregnancy. The second approach is to perform IVF on harvested eggs (without testing the polar bodies) and allow them to develop in culture to the blastomere, or eight-cell stage. A single cell is then microdissected from each blastomere and analyzed for the presence of mutations or an abnormal chromosome number. Only unaffected embryos are subsequently transferred to the uterus. The greater the number of embryos created, the greater the likelihood of a genetically normal

Figure 3.7. Preimplantation genetic diagnosis (PGD). Individuals who undergo PGD begin the process as they would for *in vitro* fertilization. The ovary is stimulated to produce mature oocytes, which are then harvested for fertilization outside of the woman's body. These mature oocytes can be used for polar body analysis or fertilized and processed for a blastomere biopsy. This figure describes the path toward the preimplantation diagnosis using both methods. Polar body analysis is limited to those disorders or variations that would be present in the maternal genetic material whereas an embryo biopsy can analyze both maternal and paternal genetic contributions. As with *in vitro* fertilization, not all pregnancies will progress to term. Prenatal diagnosis at a later stage of gestation via CVS or amniocentesis is recommended to confirm an accurate diagnosis.

embryo. Approximately 30% of implanted embryos will survive to birth, but success is impacted by maternal age and other maternal factors. As diagnosis from a single cell remains a technical challenge and the risk of misdiagnosis cannot be eliminated (Wilton, Thornhill, Traeger-Synodinos, Sermon, & Harper, 2009), confirmatory prenatal diagnosis via CVS or amniocentesis is recommended after PGD.

As NGS and **whole-exome sequencing** become more accessible, care should be given to ethical considerations for the use of PGD outside of its original goals (Stern, 2014). PGD could theoretically be used to screen for or against particular traits rather than medical conditions, bringing us closer to the idea of “designer” infants. This would obviously be ethically suspect. It is important that regulating bodies, medical and legal organizations, patient advocacy groups, and government organizations stay engaged in the discussion of these issues.

Additional options within ART include artificial insemination or IVF with donor sperm or IVF using donor egg. Couples considering these options should assess 1) how donors are screened, 2) what carrier testing is performed to ensure that the donor and patient are not carriers for variations in genes for the same genetic disease, and 3) the donor’s family history such as birth defects or known genetic conditions.

Another ART is intracytoplasmic sperm injection (ICSI), a technology available for men who have a low sperm count or poor sperm motility (Palermo et al., 1998). Sperm from the prospective father are harvested, and the cytoplasmic portions of the sperm are removed. The nucleus of the sperm is then introduced into a harvested egg by microinjection, and the developing blastocyst (early embryo) is subsequently transferred into the uterus. Single-embryo transfer is the most effective option to reduce the risk of multiple births (Tobias, Sharara, Rranasiak, Heiser, & Pickney-Clark, 2016). For approximately 1% of conceptions accomplished through ICSI, sex chromosome aneuploidy (e.g., an extra X or Y chromosome) has been reported. Although there had been concern about a 6.5% malformation rate secondary to the ART, recent data support other confounding factors that may be responsible for the increased identification of birth defects (Parazzinin et al., 2015).

All of these options are costly in terms of physical, emotional, and financial resources. At present these services are not always covered by health insurance plans. The risk of multiple gestations is also a concern, particularly if fetal reduction (i.e., abortion of one or more fetuses) is not an option the parents are willing to consider. Publications from Europe, the United States, and Australia have suggested an association between ART

and imprinting (epigenetic) disorders such as Beckwith-Wiedemann syndrome (Chapter 1; Appendix B). However, because the absolute risk is small, routine screening for these imprinting disorders in children conceived by ART is not recommended at this time (Manipalviratn, DeCherney, & Segars, 2009).

When considering ART, couples should request detailed information regarding the techniques that are used, the risk of error in diagnosis, the risk of other anomalies or birth defects, the cost per attempt, the rate of successful pregnancies, and the risk of multiple gestations (e.g., twins or triplets; Stern, 2014; Wen et al., 2010). The American Society of Reproductive Medicine and the Society of Assisted Reproductive Technology are putting forth guidelines for using ART (<http://www.asrm.org>; <http://www.sart.org>). These sites have valuable information for patients and providers about the process and data from participating centers.

PSYCHOSOCIAL IMPLICATIONS OF PRENATAL TESTING

With prenatal screening and testing technology progressing rapidly, choices can be overwhelming for a family. Health care professionals and patients often avoid difficult preliminary discussions about how a couple would respond to the diagnosis of an abnormality or, if they already have a child with special needs, how they would respond to the recurrence of the disorder in a subsequent child. For some couples, having advanced knowledge allows for preparation prior to birth; for others, it may mean ending a pregnancy.

Many of these issues are best addressed prior to attempting a pregnancy to ensure that prenatal diagnostic techniques, genetic screening, and other specialized tests can be discussed in advance. Exploring each individual’s reproductive choices and available options is time consuming, but necessary. It is imperative that health care professionals focus on the family’s psychosocial needs along with the clinical information.

When a woman gives birth to a child with special needs or a child who does not survive long after birth, the experience can be devastating. Each family is unique, and assumptions by health care providers as to what a family should or should not do in a given situation must be avoided. Genetic counselors and medical geneticists who are trained in nondirective counseling can help families understand their options and choose a course of action that is consistent with the family’s values and resources. Often, support groups or individual counseling can be beneficial.

Appropriate pretest genetic counseling should include information that is balanced (pros and cons), accurate, and up to date. It should be supported by materials that are easy to understand so pregnant women can be supported in their decision making and make an informed choice (Metcalf, 2017). This is particularly true for couples who have an increased risk for conceiving a child with a specific genetic disorder or who have previously conceived a child with a birth defect, special needs, or genetic disorder. The array of screening and diagnostic tests can be both overwhelming and reassuring. Health care providers, working together with genetics professionals, are in a unique position to help families carefully consider and understand their reproductive options and the effects that prenatal diagnosis or genetic screening will have on them physically, emotionally, and financially.

SUMMARY

- Planning for a pregnancy allows time for the patient and health care provider to address maternal health issues; start prenatal vitamins, including 0.4 mg (or more) of folic acid daily; obtain genetic carrier testing; and review family history.
- Accurate dating leads to early prenatal care and access to early ultrasound and/or blood screening tests.
- Decisions about prenatal screening (i.e., cell-free fetal DNA) versus diagnostic studies (such as CVS or amniocentesis) are complex and ideally are addressed with an individual by a genetic counselor early in pregnancy.
- Imaging studies such as fetal echocardiogram and fetal MRI may be needed to further clarify abnormal prenatal findings noted on ultrasound or through abnormal NIPT or diagnostic test results.
- Earlier diagnosis of a fetal abnormality allows couples the opportunity to explore the appropriate options for ending a pregnancy and/or to creating a delivery and management plan.
- Assisted reproductive technology such as PGD or ICSI is an important option for some women/couples.
- Genetic counselors and centers specializing in fetal care are important resources for prenatal patients and families.
- Health care workers who understand the unique stress that prenatal patients and their families may experience are instrumental in getting families through trying times. This often includes referring patients for additional counseling.

CHAPTER 4

Newborn Screening

Joan E. Pellegrino

Upon completion of the chapter, the reader will

- Understand the rationale for newborn screening
- Recognize the difference between a screening test and a diagnostic test
- Be familiar with the types of screening tests available
- Understand the limitations and pitfalls of screening

The birth of a new infant is a joyous time, but for some families a shadow is cast on their initial hopes by the worrisome results of a newborn screening test. The infant's mother will have undergone a number of screening procedures during the pregnancy (see Chapter 3), but she may be unaware that her newborn infant will also have several screening tests performed. This chapter describes the rationale for newborn screening, summarizes the types of disorders for which screening is conducted, and reviews the methods for ensuring proper follow-up on the results of newborn screening.

■ ■ ■ CASE STUDY

Denise, a 31-year-old healthy woman, was pregnant with her second child. The pregnancy was uncomplicated. She had a normal maternal serum screening test in the second trimester and normal prenatal ultrasounds. The delivery was uncomplicated, and she and her daughter, Ashley, were discharged home from the hospital when Ashley was 2 days of age. Ashley's parents were therefore upset and confused to receive a telephone call 4 days later, notifying them that Ashley had screened positive for medium chain acyl-CoA-dehydrogenase deficiency (MCAD), an inborn

error of metabolism. They did not know what this disease was, and they did not understand why Ashley should screen positive for an "inherited" condition when they already had a healthy 2-year-old daughter at home. Denise did recall reading that her state had implemented expanded newborn screening, but she was unsure what this meant. Ashley was seen by her pediatrician and underwent diagnostic testing for MCAD. The diagnosis was confirmed, and Ashley was treated with a frequent, regular feeding schedule and remained asymptomatic (see Chapter 16).

Thought Question:

How often do we miss a genetic diagnosis as a cause of developmental disabilities, and could earlier diagnosis and treatment improve the outcome in many of these cases?

WHAT IS A SCREENING TEST?

A **screening test**, as the name implies, is a test designed to screen for, but not definitively diagnose, a particular condition. When applied to a group of individuals,

a screening test separates those who are at increased risk for a condition from those who are at a lower risk. The ideal screening test would perform this operation with perfect accuracy, but in reality, all screening tests produce **false-positive results** that identify unaffected individuals as being at increased risk. Some screening tests also produce **false-negative results**, identifying affected individuals as not being at increased risk. As the goal of newborn screening is to identify *all* truly affected individuals, interpretive methods and screening algorithms are devised to decrease false-negative results while still trying to minimize false positives. In some cases, this is accomplished by setting a numerical cut-off for a test that favors the identification of truly affected individuals at the expense of over-identifying some unaffected individuals (Figure 4.1). Since any particular condition tested for by newborn screening is relatively rare, the number of individuals affected by that condition will be much smaller than the number of unaffected individuals. Depending on the technology used, this means that some positive screens may turn out to be false positives. For some conditions, retesting a child using the same or alternative screening tests will improve the screening process, but ultimately, a final group of individuals with positive screening results must undergo diagnostic testing. A **diagnostic test** is designed to more definitively confirm or exclude the presence of a disease or condition in a particular individual (i.e., to “make a diagnosis”). Diagnostic tests are meant to be done on individual patients and differ from population-based screening tests (“risk assessments”).

WHY SCREEN NEWBORNS?

Of the hundreds of diseases and conditions that may potentially affect infants and young children, a limited number are appropriate for inclusion in a newborn screening program. In the United States, the number of conditions that are screened varies widely among the individual states. In 2005, the American College of Medical Genetics completed a report commissioned by the Health Resources and Services Administration that recommended universal screening for 29 specific core conditions and 25 secondary conditions (Newborn Screening Expert Group, 2005). The Advisory Committee on Heritable Disorders in Newborns and Children meets quarterly to review new conditions to add to the core screening panel (U.S. Department of Health and Human Services, 2018). As of September 2017, there are 34 disorders on the recommended uniform screening panel (Table 4.1) and another 26 secondary targets (Table 4.2). In general terms, the core conditions screened for must meet three criteria: They must be 1) serious (life threatening or life altering), 2) identifiable (a biomarker is available), and 3) treatable. In this context, being “treatable” does not necessarily mean that the condition is curable; it means that interventions should result in significant amelioration of the expected consequences of that condition. The types of diseases and disorders screened for generally fall into one of four categories: endocrine disorders, hemoglobinopathies, metabolic disorders, and other disorders (including immune disorders). While infectious

Figure 4.1. Setting a cut-off level for a screening test. In this example, a hypothetical screening test is applied with the ultimate goal of identifying individuals who are affected by a particular disease or condition. Individuals who ultimately prove to be unaffected show test results from 0 to 7 units; individuals who prove to be affected show test results ranging from 5 to 11 units. Individuals with test results above 7 or below 5 will be definitely identified by the screen as affected or unaffected; individuals testing between 5 and 7 may or may not be affected. If cut-off “A” is selected, all affected individuals will be correctly identified, but some unaffected individuals will be incorrectly identified as having disease (false positives). Because the number of unaffected individuals is so much larger than the number of individuals with disease, the majority of individuals testing positive will turn out to be unaffected. If cut-off “B” is selected, all unaffected individuals will be correctly identified, but some individuals with disease will be missed (false negatives). Selecting a cut-off level between “A” and “B” will result in a mix of false positives and false negatives.

Table 4.1. Recommended uniform screening panel—Core conditions

Type of disorder	Specific disorder
Amino acid disorders	Argininosuccinic aciduria (ASA) Citrullinemia type I Homocystinuria Maple syrup urine disease (MSUD) Phenylketonuria (PKU) Tyrosinemia type I
Organic acid disorders	3-hydroxy-3-methylglutaric aciduria (HMG) Glutaric acidemia type 1 (GA1) Isovaleric acidemia (IVA) 3-methylcrotonyl-CoA carboxylase deficiency (3-MCC) Holocarboxylase synthetase deficiency Methylmalonic acidemia (cobalamin disorders) Methylmalonic acidemia (mutase deficiency) Beta-ketothiolase deficiency Propionic acidemia (PA)
Fatty acid oxidation disorders	Carnitine uptake defect/carnitine transport defects Long chain L-3 hydroxyacyl-CoA dehydrogenase deficiency (LCHAD) Medium chain acyl-CoA dehydrogenase deficiency (MCAD) Trifunctional protein deficiency (TFP) Very long chain acyl-CoA dehydrogenase deficiency (VLCAD)
Hemoglobinopathies	Hb S/S; Hb S/βTh; Hb S/C
Endocrine disorders	Congenital adrenal hyperplasia Congenital hypothyroidism
Other	Biotinidase deficiency Cystic fibrosis Classical galactosemia Hearing loss Severe combined immune deficiency (SCID) Glycogen storage type 2 (Pompe) Mucopolysaccharidosis type 1 (Hurler) X-linked adrenoleukodystrophy Critical congenital heart disease

Sources: National Newborn Screening and Genetics Resource Center (2017) and U.S. Department of Health and Human Services (2018).

diseases are not part of the uniform panel, they are screened by some states and discussed below. In addition to disorders screened by blood, the panel has also recommended two disorders that are screened for by point-of-care studies performed in the nursery: hearing loss using a hearing screen (Choo & Meinzen-Derr,

2010; Wolff et al., 2010) and critical congenital heart disease (CHD) using the oxygen saturation measurement (Bruno & Havranek, 2015).

This chapter focuses on medical conditions that can be identified by newborn screening and that place the child at significant risk for developmental disabilities.

Table 4.2. Recommended uniform screening panel—Secondary targets

Type of disorder	Specific disorder
Amino acid disorders	
	Argininemia
	Citrullinemia II
	Defects of biopterin cofactor biosynthesis
	Defects of biopterin cofactor regeneration
	Hypermethioninemia
	Benign hyperphenylalaninemia
Organic acid disorders	
	2-methylbutyrylglycinuria (2MBG)
	2-methyl-3-hydroxybutyric aciduria (2M3HBA)
	3-methylglutaconic aciduria (3MGA)
	Isobutyrylglycinuria (IBG)
	Malonic acidemia (MAL)
	Methylmalonic academia with homocystinuria
	Tyrosinemia types II and III
Fatty acid oxidation disorders	
	2,4 dienoyl-CoA reductase deficiency (DE RED)
	Carnitine palmitoyltransferase I and II (CPT I and II)
	Carnitine acylcarnitine translocase deficiency (CACT)
	Medium-chain ketoacyl-CoA thiolase deficiency (MCKAT)
	Medium/short-chain L-3 hydroxyacyl-CoA dehydrogenase deficiency (M/SCHAD)
	Glutaric acidemia type II
	Short chain Acyl-CoA dehydrogenase deficiency (SCAD)
Other disorders	
	Galactokinase deficiency
	Galactose epimerase deficiency
	Other hemoglobinopathies
	T-cell-related lymphocyte deficiencies

It should be noted, however, that newborn screening is also conducted for additional conditions that carry significant medical and related emotional issues but do not place the infant at increased risk for developmental disabilities. These include congenital adrenal hyperplasia (White & Medscape, 2009), cystic fibrosis (Southern, Mérelle, Dankert-Roelse, & Nagelkerke, 2009), and sickle cell anemia/hemoglobinopathies (Benson & Therrell, 2010).

Hearing Loss

Infants are screened for hearing loss at the hospital where they are born. This is typically done at the bedside and is thus referred to as a point-of-care service. The incidence of severe to profound hearing loss is 1 out of 1,000, but it increases to 6 out of 1,000 when you include mild to moderate hearing loss. By 18 years of age, 17 out of 1,000 persons will be affected by some degree of permanent hearing loss (Grindle, 2014). In

2014, 97% of newborns were screened for hearing loss in the United States (current data are available at <http://www.cdc.gov/ncbddd/hearingloss/data.html>). The goals of screening for hearing loss are to 1) identify all children with a permanent loss by age 3 months, 2) initiate appropriate interventions by age 6 months, 3) establish a medical home for infants with permanent hearing loss, and 4) track data and quality metrics for public health initiatives. With the introduction of newborn hearing screening, the mean age of diagnosis of hearing loss has decreased from 2.5 years to 2 to 3 months of age. A detailed discussion of newborn hearing screening can be found in Chapter 7, and a discussion of the causes and interventions for hearing loss can be found in Chapter 26.

Critical Congenital Heart Disease

CHD is the most common congenital malformation, with an incidence of 8 to 12 per 1,000 live births. Critical

CHD (CCHD) occurs in about 1.5 per 1,000 newborns, accounting for 10%–15% of all heart defects. These are called critical defects as they require intervention in the first weeks of life or may cause significant morbidity (including developmental disabilities) or mortality (Frank, Bradshaw, Beckman, Mahle, & Martin, 2013). In one study, 50% of infants with previously undiagnosed CCHD died at home or in emergency departments (Chang, Gurvitz, & Rodriguez, 2008). Typically, these types of heart defects lead to low levels of oxygen in the newborn period and may be identified using **pulse oximetry screening** (a noninvasive method for monitoring oxygen saturation) at least 24 hours after birth. Some specific types of CCHDs are listed in Table 4.3. In September 2011, the U.S. Health and Human Services (HHS) Secretary added universal screening discharge pulse oximetry to the recommended universal screening panel in an effort to better identify asymptomatic infants with CCHD prior to discharge from the newborn nursery. Some states have been slow to recommend universal screening for these disorders due to problems with implementation (Studer, Smith, Lustik, & Carr, 2014). About 30 states have already implemented CCHD universal screening, and the remaining states either have some population screening or are working on implementation.

Endocrine Disorders

The endocrine system produces and regulates a variety of hormones that are critical to maintaining the body in a normal and balanced physiological state, called **homeostasis**. Several specific hormones are critical to the early growth and development of the central nervous system. Congenital hypothyroidism is a condition in which a newborn produces an inadequate amount of thyroid hormone. One in 3,000 infants is born with

the condition, making it relatively common compared with many other disorders screened for in the newborn period. This is usually not due to a genetic defect. Early identification of this condition allows for early treatment with thyroid hormone replacement. Untreated infants have severe growth problems and atypical brain development, resulting in serious lifelong intellectual disability (Fingerhut & Olgemöller, 2009; Pass & Neto, 2009).

Infectious Diseases

At the time of this writing, three states screen for human immunodeficiency virus (HIV), and another two states screen for *Toxoplasmosis gondii*. These are potentially serious infections in newborns. A positive screen for either of these organisms would require consultation with an infectious disease specialist for confirmation and treatment.

A positive HIV screen in the newborn indicates that the mother is infected and the newborn needs to be followed for the increased risk of disease. The goal of treatment for affected newborns with HIV is long-term suppression of viral replication with antiretroviral therapy (ARV) in order to prevent clinical symptoms of acquired immunodeficiency syndrome and to preserve the child's immune system. Guidelines for treatment are available via the HHS (see <https://aidsinfo.nih.gov/>). All pregnant women are offered HIV screening prenatally; this ensures that pregnant women who test positive can start ARV treatment and reduce the risk of "vertical" transmission to the fetus. As a result, there has been a more than a 70% reduction in the transmission of HIV from an infected mother to her newborn infant in the United States (Connor et al., 1994).

Untreated congenital toxoplasmosis results in multisystem disease, including seizures, visual impairments, and intellectual disability. The incidence of congenital toxoplasmosis ranges from 1 in 1,000 to 1 in 8,000 live births. Infants identified through newborn screening require treatment with pyrimethamine, sulfadiazine, and leucovorin over a year to reduce the incidence of the above sequelae (Röser, Nielsen, Petersen, Saugmann-Jensen, & Nørgaard-Pedersen, 2010).

Immune Disorders

Severe combined immunodeficiency (SCID) includes a group of disorders that leads to early childhood death as a result of severe infections (Puck, 2007). SCID is also known as the "bubble boy" or "bubble baby" disease because affected children used to be placed in a protected environment to reduce the risk of infection. Children

Table 4.3. Some specific critical congenital heart diseases

Coarctation of the aorta
Double-outlet right ventricle
d-Transposition of the great arteries
Ebstein anomaly
Hypoplastic left heart syndrome
Interrupted aortic arch
Pulmonary atresia (with intact septum)
Single ventricle
Total anomalous pulmonary venous return
Tetralogy of Fallot
Tricuspid atresia
Truncus arteriosus

receiving an early diagnosis via screening can benefit from hematologic stem cell transplantation (Lipstein et al., 2010). SCID was added to the recommended uniform screening panel in 2010 (see <https://www.hrsa.gov/advisory-committees/heritable-disorders/index.html>). As of 2018, it is being screened for in most states.

Metabolic Disorders

Metabolic disorders, also known as inborn errors of metabolism, represent a diverse group of genetic conditions that manifest as impairments of body chemistry at the cellular level (see Chapter 16). These conditions are often associated with the accumulation of atypical substances, or metabolites, in body fluids and tissues as a consequence of atypical functioning of proteins known as enzymes. Phenylketonuria (PKU) is a classic example of a screenable metabolic condition. In the United States, the incidence of PKU is 1 in 10,000, with an increased incidence in Caucasians of European decent. The disorder belongs to a group of metabolic conditions known as **amino acid disorders**. In PKU, a genetic mutation results in the deficiency of an enzyme needed to process phenylalanine, an amino acid common to most protein-laden foods, including meat and dairy products. Early identification of PKU by newborn screening allows implementation of a protein-restricted diet. In the absence of treatment, there is an accumulation of phenylalanine in blood and body tissues, with particularly severe consequences for the developing central nervous system.

Another relatively common metabolic disorder (with an incidence of 1 in 15,000) is MCAD, the disorder that Ashley has, as discussed in the opening case study. This disorder is the most common example of a group of metabolic conditions called **fatty acid oxidation disorders** (Kompore & Rizzo, 2008; Leonard & Dezateux, 2009). Normally, the body processes fat in order to release energy through oxidation. This is especially important during periods of fasting, when fat becomes the main source of energy for the body. Children with MCAD

may become seriously ill after a period of fasting and may suffer permanent brain damage as a consequence of hypoglycemia. Careful monitoring and frequent feedings are essential, especially during infancy.

In addition to amino acid and fatty acid disorders, there are several other categories of metabolic diseases for which newborn screening is available. These include certain **urea cycle disorders**, **organic acidemias**, disorders of carbohydrate metabolism (e.g., **galactosemia**), and several miscellaneous enzyme deficiencies (e.g., **biotinidase deficiency**). These disorders are amenable to dietary intervention or to specific medical treatments. The newest group of disorders added to the uniform panel is storage disorders. These may be treatable with enzyme replacement therapy or stem cell transplant. **Pompe** (see Box 4.1) is a glycogen storage disorder that was added to the recommended universal screening panel in 2013. In 2015, both **mucopolysaccharidosis type 1** and **X-linked adrenoleukodystrophy** were added. As a group, the metabolic disorders now represent the largest number of potentially treatable conditions that can be identified through newborn screening and are the primary targets of the newest screening technologies.

HOW IS NEWBORN SCREENING DONE?

Most newborn screening tests rely on blood samples obtained during the first few days after birth (Fernhoff, 2009; Hiraki & Green, 2010; Levy, 2010). Testing begins by collecting a blood sample from a heel prick and blotting this onto a special filter-paper collection device. The sample is collected before the newborn is discharged from the birthing facility but after the infant has had an opportunity to feed, ideally at least 24 hours after birth. The infant must eat first because certain metabolic disorders cannot be detected until the body is challenged to metabolize the substances present in breast milk or formula. The filter paper is dried and sent to a newborn screening laboratory, usually a state Department of Health facility. The specimen is then divided into

BOX 4.1 EVIDENCE-BASED PRACTICE

Pompe's Addition to the Recommended Universal Screening Panel

Each disorder on the recommended uniform screening panel has an associated algorithm that helps clinicians decide what tests are needed in order to confirm or rule out a positive screen. When a new disorder is added to the newborn screening panel, then new algorithms and evidence-based treatment guidelines need to be devised. Pompe was approved in March 2015, and the Pompe Disease Newborn Screening Working Group recently published guidelines for the initial evaluation (algorithms) and management of confirmed positive patients (Burton et al., 2017).

multiple samples for use in a variety of tests screening for specific diseases. In the past, a different test was required for each disease. With the advent of tandem mass spectrometry, the number of tests that can be run on one sample has increased exponentially.

The mass spectrometer is a device that separates and quantifies ions based on their mass-to-charge ratio (American College of Medical Genetics & American Society of Human Genetics, 2000). The **tandem mass spectrometer (MS/MS)** consists of two of these devices separated by a reaction chamber such that accurate measurements of many different types of metabolites can be obtained at once (Chace, DiPerna, & Naylor, 1999). This is a very rapid and sensitive method for mass screening because a single sample can be screened in 1–2 minutes for numerous disorders (Chace, Kalas, & Naylor, 2003). This technology can improve the detection rate (lower the number of false positives) for diseases such as PKU (Marsden, Larson, & Levy, 2006). It is important to note that not all of the currently mandated disorders can be screened in this way, so other methods will continue to be needed.

Many states have second-tier testing if the initial biochemical test is found to be atypical. Second-tier testing is usually performed by the same laboratory that performed the initial screen and occurs automatically as part of the screening algorithm. Under this method, a sample is tested and flagged as atypical relative to an expected range for the test. The sample is then sent for a second-tier test that aids in the interpretation of the initial screening result. For example, a specimen might be atypical for immunoreactive trypsinogen (IRT), a test for cystic fibrosis. That sample may then be tested for at least some of the common DNA mutations associated with cystic fibrosis. If one or two mutations are found, the sample may be coded as positive. If no mutation is found then the sample may be coded as negative or positive depending on the level of IRT. Second-tier testing may involve genetic testing (testing of the DNA of the infant, see Chapter 1). By adding second-tier testing (such as DNA), the sensitivity of the test is increased. However, an increased number of carriers (false positives—individuals with a single copy of the mutated gene who actually do not have cystic fibrosis) are also identified (Baker et al., 2016).

WHAT SHOULD BE DONE WHEN A CHILD HAS A POSITIVE NEWBORN SCREEN?

In practice, each state decides how to handle positive screening results and how to follow up. In general, there should be prompt notification of the physician of

record (usually the primary care pediatrician or family practitioner) and the infant's family. Definitive testing should confirm the diagnosis. If the diagnosis is confirmed, a treatment plan specific to that disorder should be initiated. The family is typically referred to a specialty consultant or program, and genetic counseling is offered. Some of the conditions screened for require urgent evaluation and onset of therapy, such as organic acidemias, carbohydrate and urea cycle disorders, and immune and endocrine diseases. All interventions require close collaboration among the medical specialist, primary care physician, public health department, and the family.

Even when the follow-up plan for a positive newborn screen operates efficiently and effectively, families experience significant stress related to the process. As previously discussed, many positive screens turn out to be false positives. In many conditions, for every 10 infants with a positive screen, only 1 will be found to actually have the disease. Even though these other 9 infants will ultimately prove to be unaffected, the process leading to this conclusion can be difficult for families. Mothers of false-positive infants have been found to have significantly increased stress level scores compared with mothers of screen-negative infants, and they score higher on measures of parent–child dysfunction. Having the child seen at a specialty center (e.g., a metabolic or genetic disorders clinic at an academic medical center) or communicating repeat screening results in person seems to improve this situation (Waisbren et al., 2003). While it is important for families to understand that a positive newborn screen does not automatically mean that their infant has a problem, it is equally important that appropriate follow-up is pursued in a timely fashion to allow identification of truly affected infants.

WHAT HAPPENS TO CHILDREN WITH CONFIRMED DISEASE?

Infants with a positive newborn screen are often referred to a center where they can be seen by a medical specialist who has expertise in the condition for which positive screening occurred (James & Levy, 2006). This may be a hematologist, a pulmonologist, an endocrinologist, an infectious disease specialist, or a geneticist. In some states, families may have access to multidisciplinary clinics that include nurses, genetic counselors, social workers, and nutritionists in addition to pediatrician specialists. The specialist conducts additional testing to confirm the specific diagnosis or to aid in genetic counseling. Once the diagnosis is established, the child will require ongoing (and often lifelong) care

for that condition. The specific interventions employed will depend on the diagnosis (e.g., see Chapter 16). In general, the focus is to provide long-term therapy for the child and ongoing counseling to the family, with the ultimate goal of improving medical, neurodevelopmental, and psychosocial outcomes. Some disorders are relatively easy to manage with medications or supplements (e.g., thyroid hormone replacement therapy for congenital hypothyroidism or biotin therapy [a B vitamin] for biotinidase deficiency). Other disorders are more complex and may require a combination of medications, supplements, and dietary changes. For example, the treatment of PKU requires protein restriction and replacement of normal food items with synthetic, non-phenylalanine-containing substitutes and medication. This is usually achieved using special formulas (medical food) in infants and young children or supplemental nutrition bars in older children and adults. Although this sounds quite simple, for most individuals and families it is a very burdensome diet and is complicated by the fact that these specialized foods are costly and may not be covered by medical insurance. The cost of medication is a significant problem for individuals with storage disorders, as enzyme replacement therapy can cost hundreds of thousands of dollars each year (see Chapter 16).

As most of these disorders are inherited, genetic testing may be recommended to confirm the diagnosis or to provide additional prognostic information. Once a specific mutation is identified, prenatal diagnosis may be available for the next pregnancy if the family chooses to pursue this (see Chapter 3). The **recurrence risk** (risk that another child will be born with the same condition in the future) is an appropriate concern. Because most metabolic disorders are inherited as autosomal recessive traits (see Chapter 1), the statistical risk of recurrence is 25%.

WHAT IS THE RISK OF DEVELOPMENTAL DISABILITY IN CHILDREN WITH CONFIRMED DISEASE?

The neurodevelopmental and functional sequelae of a particular disorder identified through newborn screening is specific to that disorder. Unidentified and untreated these disorders invariably lead to significant morbidity. A few studies have addressed the issue of developmental outcomes in children who have an underlying metabolic disorder and were diagnosed by newborn screening. In one study (Waisbren et al., 2003), the children identified by newborn screening had fewer developmental and health problems and functioned

better (as evidenced by developmental testing) compared with those children diagnosed at a later age based on clinical symptoms. The children identified through screening had fewer hospitalizations, shorter hospital stays, and 60% fewer medical problems, and they scored significantly higher on developmental testing. Despite this positive outlook, many of these diseases, especially the storage disorders, are still associated with severe developmental disabilities (Dhondt, 2010).

HOW CAN SCREENING FAIL?

There are a number of steps during which newborn screening can fail. First, the newborn may have been missed being screened at the hospital. Second, many states allow for exemptions from newborn screening based on religious or other reasons. Other possibilities are that the newborn may have been born at home, the newborn may have been transferred to another hospital, or the specimen could have been lost or misidentified. There are also reasons why an infant could screen negative but still have a disease (i.e., a false-negative result). For example, it is possible that the specimen was obtained too early. As previously noted, for some of the metabolic disorders, the infant needs to be at least 24 hours old and must have been fed an adequate amount of formula or breast milk before a screening test can be valid. If the infant has not eaten, then the metabolites for some of the diseases will not accumulate and the test will yield a false-negative result. For some disorders, the test is not accurate if the infant has had a blood transfusion. Things as simple as how much blood is collected, how long the sample is dried, how long it took to get to the state lab, and even the weather conditions during shipment can result in inaccurate test results. In addition, infants are sometimes “lost” to follow-up. It may be difficult to actually locate a specific infant due to a name change for the infant, family relocations, inadequate information provided with the sample (e.g., wrong address or telephone number), or a new physician of record.

Newborn screening can be particularly challenging in infants who are born prematurely or are critically ill in the neonatal intensive care unit. The false-positive rate increases with decreasing birth weight and gestation age and is significantly increased in very-low-birth-weight neonates (< 1,000 g) and infants with a gestational age of greater than 32 weeks. Strategies to decrease the false-positive rate include waiting for greater than 48 hours to obtain the first sample in infants with a gestational age of less than 32 weeks (Slaughter et al., 2010) and stopping nutrition 3 hours before sample collection (Morris et al., 2014).

The purpose of newborn screening is to identify affected infants, but as previously noted, a certain number of unaffected infants will be identified as being at risk. For some conditions, these false-positive cases turn out to represent individuals who are carriers for the condition. With the advent of DNA testing, an increasing number of carrier infants have been identified. These infants do not have the disease but are carrying one DNA mutation for the screened disease. In many cases, the families of these newborns will be referred to a specialty center for further testing and counseling. If it is determined that the infant is a carrier, then genetic counseling will be offered to the parents so that they can better understand the risk of recurrence for themselves, for their child (and his or her future children), and for the child's siblings (who may also be carriers for the condition).

THE PAST, PRESENT, AND FUTURE OF NEWBORN SCREENING

The first successful newborn screening program was started in Massachusetts in 1962 with screening for PKU (MacCready, 1963). Preventive screening was mandated by the state and subsequently adopted by other states over a period of several years. Expansion of newborn screening began in earnest in 1975, when a test was developed to screen for congenital hypothyroidism (Dussault et al., 1975; LaFranchi, 2010). The success of newborn screening for this disorder led to the addition of testing for an increasing number of disorders. Each year more than 4 million newborns are screened in the United States for a variety of disorders, and approximately 6,000 infants are diagnosed with a detectable and treatable disorder (National Newborn Screening and Genetics Resource Center, 2017; U.S. Department of Health and Human Services, 2018). Each state decides which disorders will be screened for, but the majority of states are providing universal screening for most of the 34 core conditions. Most states have mandatory screening (i.e., all newborns must be screened) with implied consent. Some states have a single designated laboratory that performs all screening testing; others contract with regional centers, university laboratories, or private laboratories. Each state must decide how the screening process is to be conducted, how to notify the parents and professionals of the results, and how to follow up on atypical results. Each state may make a different decision depending on a number of factors including its resources, population mix, and birth rate. However, with the passage of The Newborn Screening Saves Lives Act of 2008, most states have begun to

follow a uniform practice for performing and following up on newborn screening (National Newborn Screening and Genetics Resource Center, 2017).

Further expansion of screening programs has been driven by consumer activism and new technologies (especially tandem mass spectroscopy). The HHS Secretary's Advisory Committee on Heritable Disorders in Newborns and Children has developed an evidence review process to consider additional conditions for universal screening. As of September 2017, they have evaluated 12 conditions and recommended the addition of 5 to the uniform panel. The advisory committee looks at the scientific evidence to make recommendations for inclusion in the screening panel by reviewing the condition, diagnosis, treatment, and screening methods. They consider the natural history of the disease, at how early and by what method the disease is diagnosed, and at the clinical variability and burden of disease. They also review information on the methods available for newborn screening, including the validity, sensitivity, positive-predictive value, cost, and whether or not it can be multiplexed (more than one disease identified from the same run). Then they review the diagnosis and treatment options to see if confirmation of the diagnosis is available and if early identification and treatment can improve the outcome (Calonge et al., 2010).

A state can also add diseases to their newborn screening panel through their own legislative acts. Therefore, some conditions that were not recommended by the advisory committee are, in fact, being tested for in a few specific states. The lysosomal storage disorders are a good example of this. These are a group of about 40 diseases in which there is progressive accumulation of a substance in the **lysosome** (a cellular organelle containing degradative enzymes) that is normally broken down. In lysosomal storage disorders, the substance is unable to be metabolized due to a defect in an enzyme. Some of these disorders are treatable by either enzyme replacement therapy or hematopoietic stem cell transplantation. However, in order to optimize treatment, it should begin as soon as possible, making early identification critical. Table 4.4 includes a variety of disorders, including lysosomal storage diseases, that are being screened for in at least one state. As new technologies are developed and therapeutic advances are made, the list of conditions recommended for newborn screening is likely to expand. As an example, with the completion of the Human Genome Project, the discovery of hundreds of mutations causing disorders being screened for opens the possibility of using expression microarray technology to screen for these mutations in the newborn period rather than to screen for metabolic impairments resulting from the mutations (the MS/

MS method). Chromosomal microarray has become the first-tier test for individuals with developmental disabilities or congenital anomalies (Miller et al., 2010; also see Chapter 1). This technology could be used for newborn screening as well. Whole-genome sequencing studies have also been piloted for newborn screening (Bodian et al., 2016).

There is no doubt that newborn screening will expand in the future. The challenge will be to balance the legal, ethical, and social concerns that can be raised by expanded screening (DeLuca, 2017). As an example, there is clinical variation in many of the screenable diseases, making it difficult to know who to treat and when to institute therapy. Furthermore, DNA-based technology can detect carriers and also detect sequence variations and polymorphisms for which we have little information, making it difficult to know the clinical significance (Bodian et al., 2016). There may also be a paradigm shift from the newborn as the patient to the family as the patient. In this view, the family receives the information on carrier status and its implications for prenatal diagnoses in future pregnancies (McCabe & McCabe, 2008).

SUMMARY

- Screening tests are important tools used to help define increased risk for significant medical and genetic conditions.
- Screening tests can be used for mass screening of newborns, prenatal screening, and targeted screening of at-risk populations and ethnic groups.

- Newborn screening is an important and effective public health measure.
- Many infants have been identified by screening and have been successfully treated with improved outcomes though they may have lifelong complications.
- The number of disorders screened for has grown over time and will continue to increase.
- Parents have been the greatest advocates for expanding newborn screening and will continue to play a major role as we move forward (Lipstein et al., 2010).
- As more infants are identified with more disorders, future research will be aimed at developing innovative therapies to further improve outcomes.

CHAPTER 5

Premature and Small-for-Dates Infants

Khodayar Rais-Bahrami and Billie Lou Short

Upon completion of this chapter, the reader will

- Recognize some of the causes of prematurity and reasons that infants may be small for their gestational age
- Be able to identify physical characteristics of the premature infant
- Understand the complications and illnesses associated with preterm birth
- Be aware of the methods used to care for low birth weight infants
- Know the results of outcome studies

The preterm infant is at an immediate disadvantage compared with the full-term infant. In addition to facing all of the usual challenges of making the transition from intrauterine to extrauterine life, the preterm infant must make these changes using organs that are not yet ready to perform the task. Almost every organ is immature (Hyman, Novoa, & Holzman, 2011). Decreased production of a substance called surfactant in the lungs can lead to respiratory distress syndrome (RDS); immaturity of the central nervous system places the preterm infant at increased risk for an **intraventricular hemorrhage (IVH)**, **periventricular leukomalacia (PVL)**, and **hydrocephalus**; and inadequate kidney function makes fluid and metabolic management difficult. An immature gastrointestinal tract impairs the infant's ability to digest and absorb certain nutrients and places the gut at risk for developing a life-threatening disorder called **necrotizing enterocolitis (NEC)** that results from inadequate blood supply to the small intestine. Finally, the preterm infant's eyes are more susceptible to the damaging effects of the oxygen

that is used to treat respiratory distress. This may result in **retinopathy of prematurity (ROP)** and the potential for subsequent vision loss (see Chapter 7). Given all the risks, it is remarkable that most preterm infants overcome these acute problems with little residual effects. A minority, however, do sustain long-term medical and neurodevelopmental complications. A discussion of these complications and their prevention is the focus of this chapter.

■ ■ ■ CASE STUDY

Erin was born prematurely, at 23 weeks' gestation, weighing less than 500 grams (about 1 pound). During Erin's first day of life, she needed artificial ventilation and surfactant therapy to keep the air passages in her lungs open. By 2 months of age, she was doing well enough to receive a pressurized oxygen–air mixture through a high-flow **nasal cannula** (nose tube), but she had brief breathing arrests (**apnea**) associated with a slowed heart rate (**bradycardia**). These problems were treated

successfully with caffeine and frequent physical stimulation. In addition, she developed NEC, leading to small bowel (intestine) perforation that required two major abdominal surgeries 10 weeks apart.

Meeting Erin's nutritional requirements was also a problem. Initially, she needed intravenous nutrition. Gradually, she was able to tolerate increasing amounts of elemental infant formula by a nasogastric (nose to stomach) tube, and by 3 months, she was strong enough to receive some of her feedings by bottle. At her 168th day of life (i.e., postconceptional age of 45 weeks), weighing 3,760 grams (8 pounds, 4½ ounces), Erin went home on oxygen and caffeine (to prevent apneic episodes) and was hooked up to an apnea monitor while taking all feedings by mouth. Her parents had been instructed how to administer oxygen therapy, how to use the monitor, and how to administer cardiopulmonary resuscitation (CPR) if she had a prolonged apneic episode. Although her overall prognosis is good, Erin will need continued medical and neurodevelopmental monitoring until she is school age.

Thought Question:

Define *SGA infants*. What are the maternal, placental, and fetal factors leading to SGA infants?

DEFINITIONS OF PREMATURITY AND LOW BIRTH WEIGHT

A preterm or premature infant is one born before or at 36 weeks' gestation. Although there is no universal system for birth weight classification, it is commonly accepted that an infant with a birth weight less than 2,500 grams (5½ pounds) is categorized as **low birth weight (LBW)**, an infant born weighing less than 1,500 grams (3⅓ pounds) is **very low birth weight (VLBW)**, and an infant with a birth weight lower than 1,000 grams (2¼ pounds) is **extremely low birth weight (ELBW)**. An infant weighing less than 800 grams (1¾ pounds) is sometimes called a **micro-preemie** (Dani, Poggi, Romagnoli, & Bertini, 2009). Assessment of gestational age is also important because LBW infants may represent prematurely born infants or those who have fetal growth restriction (see Chapter 6) and are **small for gestational age (SGA)**.

Small-for-Gestational-Age (SGA) Infants

SGA infants can be either full term or premature. In either case, they have a birth weight below the 10th percentile using a graph of population-specific birth weight versus gestational age (Figure 5.1). SGA infants are also referred to as dysmature, or small for dates. In

Figure 5.1. Newborn weight by gestational age. The shaded area between the 10th and 90th percentiles represents infants who are appropriate for gestational age. Weight below the 10th percentile makes an infant small for gestational age. Prematurity is defined as being born before 36 weeks' gestation. (From Lubchenco, L. O. [1976]. *The high risk infant*. Philadelphia, PA: W.B. Saunders; reprinted by permission.)

addition to being small, these infants appear malnourished, usually because of **intrauterine or fetal growth restriction**. About one half of SGA births are attributable to maternal illness, smoking, or malnutrition (Grivell, Dodd, & Robinson, 2009). These infants tend to be underweight but have normal length and head circumference; they are said to have asymmetric SGA because of this discrepancy in growth pattern. The other half of SGA births are said to have symmetric SGA (equally deviant in length, weight, and head circumference). These infants may have been exposed *in utero* to alcohol or to infections such as cytomegalovirus (see Chapter 6). Infants with certain chromosomal and other genetic disorders also present as symmetrical SGA infants (Adams-Chapman et al., 2013). Even in uncomplicated pregnancies, SGA infants, as compared with **appropriate-for-gestational-age** newborns, have a significantly higher risk of neonatal morbidity and mortality and of being stillborn. The following morbidities are significantly more common among term SGA neonates when compared with appropriate-for-gestational-age neonates: An Apgar less than 4 at 5 minutes, respiratory distress syndrome, requirement for mechanical ventilation, NEC, grade 2 or 3 IVH, and neonatal sepsis. SGA infants, whether full term or preterm, are recognized as having an increased risk for many other complications in the newborn period (e.g., hypoxia, hypothermia,

and hypoglycemia), increased perinatal and neonatal mortality, long-term growth impairments, and developmental disabilities (Argente, Mehls, & Barrios, 2010; de Bie, Oostrom, & Delemarre-van de Wall, 2010; Mendez-Figueroa, Truong, Pedroza, Khan, & Chauhan, 2016; Sinclair, Bottino, & Cowett, 2009).

Assessment of Gestational Age

Assessment of gestational age helps distinguish an appropriate-for-gestational-age infant from an SGA infant. In addition, it influences treatment approaches, neurodevelopmental assessment, and outcome. The gestational age is calculated from the projected birth date, or estimated date of confinement. This can be obtained using the Nägele rule: Add 7 days and subtract 3 months from the date of the last menstrual period. The accuracy of menstrual dating, however, is quite variable, especially in anticipated preterm deliveries. In most cases, uterine size is an accurate predictor of gestational age and can be measured by clinical and ultrasound examination. Another way of estimating gestational age is by noting when fetal activity first develops. **Quickening** is first felt by the mother at approximately 16–18 weeks' gestation. Fetal heart sounds can be first detected at approximately 10–12 weeks by ultrasound and at 20 weeks by fetoscope (similar to a stethoscope). Following birth, gestational age can be assessed using a clinical scoring system called the modified Dubowitz examination (discussed next). Another technique allows for estimating the degree of prematurity by examining the maturity of the lens of the eye in the first 24–48 hours of life (Nagpal, Kumar, & Ramji, 2004). Using a combination of these methods increases the accuracy of gestational age assessment.

Physical and Behavioral Characteristics of the Premature Infant

Several physical and developmental characteristics distinguish the premature infant from the full-term infant. Historically, the scoring system developed by Dubowitz, Dubowitz, and Goldberg (1970) and updated by Ballard and colleagues (1991) takes these characteristics into account and enables the physician to estimate the infant's gestational age with some accuracy (Figure 5.2). The limitation of this scoring system is the postnatal age of the infant. If the scoring is not performed within the first 24 hours of birth, neurological and some physical features (e.g., skin texture) can change, making the infant appear more mature. Also,

any severely ill infant can be difficult to evaluate due to altered neurological status.

The main physical characteristics that distinguish a premature infant from a full-term infant are the presence of fine body hair (**lanugo**) and smooth, reddish skin, along with the absence of skin creases, ear cartilage, and breast buds (Figure 5.3). In addition to the physical appearance, premature infants display distinctive neurological and behavioral characteristics, including reduced muscle tone and activity and increased joint mobility (Constantine et al., 1987). Low muscle tone is particularly evident in the infant born before 28 weeks' gestation; it gradually improves with advancing gestational age, starting with the legs and moving up to the arms by 32 weeks gestational age. Thus, while the premature infant lies in a floppy, extended position, the full-term infant rests in a semi-flexed position. As flexion tone improves over the weeks after birth, increased joint mobility disappears. Finally, as compared with the full-term infant, the premature infant may appear behaviorally passive and have disorganized movements in the first weeks of life (Mandrich, Simons, Ritchie, Schmidt, & Mullet, 1994).

INCIDENCE OF PRETERM BIRTHS

The preterm birth rate in the United States declined for the seventh straight year in 2014 to 9.57%; the LBW rate was unchanged at 8.00%. The infant mortality rate decreased to a historic low of 5.82 infant deaths per 1,000 live births (Mathews & Driscoll, 2017). While preterm birth represents a minority of pregnancies, it is responsible for the majority of neonatal deaths and nearly one half of all cases of neonatal-onset neurodevelopmental disabilities, including cerebral palsy (Stavsky et al., 2017). The risk is highest in infants born before 32 weeks' gestation, representing 2% of all births. Preterm births occur twice as frequently in African Americans as in Caucasians. Of LBW infants weighing less than 2,500 grams, 70% are preterm and 30% are full-term infants who are SGA (Heron et al., 2010; Murphy, Mathews, Martin, Minkovitz, & Strobino, 2017).

CAUSES OF PREMATURE BIRTH

Preterm delivery is certainly a cause for concern and has been associated with a number of cofactors: obstetric interventions (e.g., cesarean sections); assisted reproduction techniques (e.g., *in vitro* fertilization); multiple-gestation births; substance abuse, low socioeconomic status, and low maternal educational level;

Figure 5.2. Scoring system to assess newborn infants. The scores for each of the neuromuscular and physical signs are added together to obtain a score called the "total maturity score." Gestational age is determined from this score. (This figure was published in *Journal of Pediatrics*, 119, 418, Ballard, J.L., Khoury, J.C., Wedig, K., et al. New Ballard score, expanded to include extremely premature infants, Copyright Elsevier, 1991; reprinted by permission.)

maternal infections; and adolescent pregnancies (Cantarutti, Franchi, Monzio Compagnoni, Merlino, & Corrao, 2017). Other risk factors include inadequate prenatal care, acute and chronic maternal illness, history of previous premature pregnancies, placental bleeding, preeclampsia, smoking, and substance abuse (see Box 5.1; Cantarutti et al., 2017). Congenital anomalies or injuries to the fetus may also lead to premature birth.

Although less than 3% of all pregnancies occur in adolescents, these pregnancies account for 14%–18%

of all preterm births. A maternal age that is under 18 years is a major risk factor for complications in both mothers and neonates, especially in mothers aged younger than 15 years (Najati & Gojazadeh, 2010). Approximately half of preterm births are attributable to maternal infections, which are commonly undetected and untreated in low-income settings. In addition, up to 80% of early preterm births (births before 30 weeks' gestation) are associated with an intrauterine infection that precedes the rupture of membranes (Lee et al., 2015).

Figure 5.3. Typical physical features of a premature infant.

COMPLICATIONS OF PREMATURITY

The premature infant must undergo the same physiologic transitions to extrauterine life as the full-term infant. The preterm infant, however, must accomplish this difficult task using immature body organs. The result is a significant risk of complications in virtually every organ system, and this risk increases with the degree of prematurity.

Respiratory Problems

Respiratory problems are one of the most common and potentially life-threatening complications for

premature infants born before 34 weeks. These problems result from the immaturity of the fetal lungs and the lack of production of **surfactant**. The section that follows discusses the acute respiratory issue of hyaline membrane disease (HMD) as well as the potential long-term consequences leading to bronchopulmonary dysplasia (BPD).

Hyaline Membrane Disease HMD, also called RDS, is a disorder characterized by respiratory distress in the newborn period. The underlying impairment is decreased production of surfactant that normally keeps the **alveoli** (the terminal airway passages) open, permitting the exchange of oxygen and carbon dioxide (Figure 5.4). A chest x-ray can clinically confirm HMD, showing a “ground glass” appearance of the lungs. This results from the collapsed alveoli appearing dense and hazy in comparison with the air-filled lung of a typical full-term newborn, which appears translucent and black (Figure 5.5). The clinical course of HMD involves a peak severity between 24 and 48 hours after birth, followed by improvement over the next 24–48 hours. In uncomplicated cases, HMD will resolve within 72–96 hours after birth. This classical course of HMD has fortunately been modified by the administration of exogenous surfactant replacement therapy (Wirbelauer & Speer, 2009). Improvement in pulmonary function usually begins within minutes after the first dose of surfactant is injected through the trachea and into the lungs of the newborn; after one or two doses of surfactant, effective gas exchange can be achieved with a significantly lower level of oxygen and ventilatory support. Except in severe cases of HMD, it is unusual for an infant to require more than two doses of surfactant.

BOX 5.1 EVIDENCE-BASED PRACTICE

Risk Factors for Preterm Delivery

Preterm delivery is a significant concern that has been associated with a number of cofactors, such as obstetrical interventions (e.g., cesarean sections), assisted reproduction techniques (e.g., *in vitro* fertilization), multiple-gestation births, substance abuse, low socioeconomic status, low maternal educational level, maternal infections, and adolescent pregnancies (Cantarutti et al., 2017). Other risk factors include inadequate prenatal care, acute and chronic maternal illness, previous premature pregnancies, placental bleeding, preeclampsia, smoking, and substance abuse (Cantarutti et al., 2017). Congenital anomalies or injuries to the fetus may also lead to premature birth.

Although less than 3% of all pregnancies occur in adolescents, these account for 14%–18% of all preterm births. A maternal age of younger than 18 years is a major risk factor for complications in both mothers and neonates, especially in mothers younger than 15 years of age (Najati & Gojazadeh, 2010). Approximately half of preterm births are attributable to maternal infections, and up to 80% of early preterm births (births before 30 weeks’ gestation) are associated with an intrauterine infection that precedes the rupture of membranes (Lee et al., 2015).

Figure 5.4. Schematic drawing of alveoli in a normal newborn and in a premature infant with respiratory distress syndrome. Note that the inflated alveolus is kept open by surfactant. Oxygen (O_2) moves from the alveolus to the red blood cells in the pulmonary capillary. Carbon dioxide (CO_2) moves in the opposite direction. This exchange is much less efficient when the alveolus is collapsed; the result is hypoxia.

Infants with mild HMD generally do well with supplemental oxygen alone or in combination with **continuous positive airway pressure (CPAP)**. CPAP involves providing a mixture of oxygen and air under continuous pressure; this prevents the alveoli from collapsing between breaths. More severely affected infants may require the placement of an endotracheal tube for mechanical ventilatory support as well as administration of surfactant. Although surfactant therapy has significantly reduced mortality in ELBW premature infants, there has been no appreciable change in long-term pulmonary and neurodevelopmental complications in these infants (Patrianakos-Hoobler et al., 2010). Therefore, close follow-up to school entry is important.

A related approach to treating surfactant deficiency is to stimulate its production. There is evidence that administration of steroids to mothers 24–36 hours before preterm delivery stimulates surfactant production and pulmonary maturation in the fetus. This lessens the likelihood and/or severity of HMD. The effect of antenatal steroids is additive to postnatal surfactant replacement therapy in reducing respiratory distress

and mortality. It is therefore recommended that steroids be given prior to birth for potential preterm delivery of fetuses between 24–36 weeks' gestational age (Roberts, Brown, Medley, & Dalziel, 2017).

Bronchopulmonary Dysplasia The improved survival of ELBW newborns has increased the number of infants at risk for various forms of long-term respiratory morbidity associated with mechanical ventilation, including **bronchopulmonary dysplasia (BPD)**. This term is generally used to describe infants who require supplemental oxygen and/or mechanical ventilation beyond 28 days postnatal age and/or corrected gestational age of 36 weeks with persistently atypical chest x-rays and respiratory examinations (e.g., rapid breathing or wheezing). BPD primarily occurs in infants who are born at less than 32 weeks' gestation and require mechanical ventilation during the first week of life for treatment of HMD. Although the frequency of BPD in VLBW neonates is high, in the majority of cases the disease is mild. Severe BPD is more common in neonates with associated comorbidities, such as late-onset sepsis or advanced **intraventricular hemorrhage (IVH)** (Kiciński, Kęsiak, Nowiczewski, & Gulczyńska, 2017).

The development of BPD has been attributed to lung injury from a combination of **barotrauma** (pressure damage from prolonged mechanical ventilation), oxygen toxicity, infection, and inflammation. The exact mechanism of BPD, however, remains poorly understood. Since the mid-2000s, newer methods of respiratory support, including high-frequency ventilation and surfactant therapy, have increased the survival rate of smaller and less mature infants, but the total number of infants who develop BPD has not decreased. BPD remains the most common chronic lung disease of infancy in the United States, with some 7,000 new cases being diagnosed each year. Long-term studies of pulmonary function in this population indicate that as these infants grow, there is clinical improvement.

Figure 5.5. Chest x-rays of a normal newborn (left) and of a premature infant with respiratory distress syndrome (right), which shows a “white out” of the lungs due to surfactant deficiency.

Yet, children diagnosed with BPD are at increased risk for developing reactive airway disease or asthma in childhood and chronic obstructive pulmonary disease in adulthood (Vom Hove, Prenzel, Uhlig, & Robel-Tillig, 2014).

Approaches to postnatal prevention and treatment of BPD have included steroid therapy, supplemental vitamin A, high-frequency ventilation, use of bronchodilators (asthma medication), and administration of diuretics (to increase urinary excretion of excessive lung fluids). The use of postnatal steroids such as dexamethasone for prevention and treatment of BPD has been a matter of controversy. Although early postnatal corticosteroid treatment facilitates extubation (removal of the breathing tube) and reduces the risk of BPD, it can cause short-term adverse effects, including gastrointestinal bleeding, intestinal perforation, hyperglycemia (high blood sugar levels), hypertension, hypertrophic cardiomyopathy (inflammation of the heart), and growth failure. There is also the potential for steroids having long-term adverse effects on physical growth and neurodevelopment. It is not unusual for infants with BPD to require supplemental oxygen, diuretics, and bronchodilators after discharge from the hospital. Even with supportive care and treatment, infants with BPD may continue to have long-term problems, including limited tolerance of physical activity, feeding difficulties that contribute to poor physical growth, excessive caloric requirement, and an increased risk of cerebral palsy and other developmental disabilities (Abman et al., 2017; Kiciński et al., 2017).

Neurologic Problems

Premature infants are also at increased risk for neurologic problems that are often linked to their respiratory problems. These problems include **intraventricular hemorrhage (IVH)** (bleeding into the brain), **periventricular leukomalacia (PVL)** (damage to the white matter of the brain), **apnea** and **bradycardia** (brief periods of respiratory arrest and heart rates slowing), and damage to hearing from antibiotic use.

Intraventricular Hemorrhage IVH, defined as bleeding into the ventricular space within the brain hemispheres, is a significant neurological complication of extremely premature infants. The risk of IVH correlates directly with the degree of prematurity. Fortunately, its incidence appears to be declining. About half of IVH cases occur during the first day of life, and 90% by the third day of life (Brouwer, Groenendaal, Benders, & de Vries, 2014). Ultrasound of the head is the most reliable and safest technique for diagnosing IVH. The American Academy of Neurology Practice

Parameter for “Neuroimaging of the Neonate” suggests that an initial screening ultrasound shortly after birth be performed on all preterm infants of less than 30 weeks’ gestation to detect evidence of IVH. In addition, they recommend a follow-up ultrasound at 36–40 weeks postmenstrual age in order to detect CNS lesions, such as PVL and **ventriculomegaly** (enlargement of the ventricles), which will affect long-term outcomes (Brouwer et al., 2014). Magnetic resonance imaging (MRI) is better than ultrasound at detecting white matter abnormalities, hemorrhagic lesions, and cysts. Emerging data are providing evidence for the importance of this imaging modality at term-equivalent as a predictor of neurological outcome in VLBW preterm infants (El-Dib, Massaro, Bulas, & Aly, 2010).

IVH is commonly graded by four levels of severity (Volpe, 2008). Grade I is defined by bleeding into the germinal matrix, a network of blood vessels in the roof of the lateral ventricles. If the hemorrhage expands beyond the germinal matrix into the ventricular system, it is Grade II. Grades I and II account for the majority of IVH cases, and significant neurological impairment is fortunately rare with these types. About 20% of hemorrhages, however, are severe enough to dilate the ventricle (Grade III) or invade the brain substance (Grade IV). Grade IV is often called *periventricular hemorrhagic infarction*. These hemorrhages can lead to PVL, or damage of the white matter surrounding the ventricles (Volpe, 2008). The long-term neurological outcome for infants with IVH is related to the severity of the hemorrhage. Cerebral palsy (with or without intellectual disability) is seen in about 30% of patients with Grade III hemorrhages and in 75% of those with Grade IV hemorrhages (Pleacher, Vohr, Katz, Ment, & Allan, 2004; Sarkar, Bhagat, Dechert, Schumacher, & Donn, 2009).

Avoidance of hypoxic–ischemic events that lead to fluctuations in cerebral blood pressure, expert delivery room stabilization, effective resuscitation and ventilation, gentle handling, and use of muscle relaxants during mechanical ventilation have all been associated with a reduction in the incidence and severity of IVH (Volpe, 2008). A number of medications have been studied for preventing or treating IVH with varied results. These include antenatal use of steroids and postnatal use of phenobarbital, vitamin K, vitamin E, indomethacin, ethamsylate, ibuprofen, and recombinant activated factor VIIa (McCrea & Ment, 2008).

Periventricular Leukomalacia PVL is the most common form of cerebral white matter injury in preterm infants and results in cerebral palsy in 60%–100% of survivors (Huang et al., 2017). The periventricular

white matter is the region of the brain closest to the ventricles. PVL occurs when this area sustains damage either due to low oxygen or low blood flow. This area is especially vulnerable to injury in the premature infant because the glial cells, a major constituent of white matter, undergo rapid growth by the end of the second trimester. During this period, they are more susceptible to injury caused by fluctuations in cerebral blood pressure. There is also evidence that **chorioamnionitis** (maternal infection involving the membranes surrounding the fetus) increases the risk of PVL (Huang et al., 2017).

PVL may occur in association with IVH or independently (Figure 5.6). The diagnosis of PVL is best made by serial cranial (head) ultrasounds that may show the development of cystic (cyst-like) lesions in the white matter. Serial cranial ultrasounds or an MRI at near-term gestation (or at term-equivalent gestation in VLBW neonates) also have been shown to be important predictors of the subsequent development of **spastic diplegia** (a form of cerebral palsy that impairs lower extremity function) and **hemiplegia** (a form of cerebral palsy that affects one side of the body (see Chapter 21). Large cysts (greater than 3 mm in diameter) place the neonate at increased risk of developing **spastic quadriplegia** (a form of cerebral palsy that affects all four limbs), visual impairment, intellectual disability, and seizures in early childhood (Huang et al., 2017).

Auditory Toxicity

ELBW infants are at increased risk for hearing loss because of multisystem illness and the frequent use of medications (such as aminoglycoside antibiotics and diuretics) and excessive environmental noise that can be toxic to the auditory system. Hearing loss is one of the most common health problems of infancy, affecting 1 in 700 to 1,000 newborns. The rate of hearing loss in preterm infants is between 2% and 15%, with the majority of the cases having no known cause (Zimmerman & Lahav, 2013). In 1995, the Joint Committee on Infant Hearing recommended that all VLBW infants undergo auditory screening. The committee further expanded this statement in 2000 to advocate testing for all newborns. The most commonly performed tests are brainstem auditory evoked response and **otoacoustic emission**, which are discussed in Chapter 7 (Ohl, Dornier, Czajka, Chobaut, & Tavernier, 2009).

Apnea and Bradycardia

Apnea is clinically defined as a respiratory pause lasting 15–20 seconds. It is usually associated with a decrease in heart rate to below 80 to 100 beats per minute (bradycardia) and systemic oxygen desaturations. It is the most common disorder of respiratory control found in the neonatal intensive care unit (NICU) and

Figure 5.6. Periventricular leukomalacia. A) The blood vessel supply to the brain, and B) the brain structures. The area of the white matter surrounding the lateral ventricle (particularly the top part) is especially susceptible to hypoxic-ischemic damage because it is not well supplied by blood vessels. It lies in a watershed area between the anterior, middle, and posterior cerebral arteries. In premature infants, poor oxygenation and decreased blood flow associated with respiratory distress syndrome may lead to necrosis of this brain tissue, a condition termed *periventricular leukomalacia*. When the posterior portion is affected, the optic radiations may be damaged, resulting in cortical blindness.

can affect up to 85%–100% of premature newborns. It is related to immaturity of the central nervous system. (Goryniak, Szczęśniak, Śleboda, & Dołęgowska, 2017).

Apnea of prematurity (AOP) remains a major clinical problem and requires the neonatologist to make treatment choices that are sometimes difficult. AOP occurs in most infants of gestational age less than 33 weeks (Goryniak et al., 2017). It is a developmental disorder that usually reflects a physiological immaturity of brain control of respiration. However, neonatal diseases may be associated with AOP and play an additive role, resulting in an increased incidence of apnea. Careful screening should therefore be performed in order to make sure that no factor other than immaturity is involved in the occurrence of apnea. Short apnea (less than 10 seconds) without bradycardia and/or desaturation is not clinically significant. Prolonged apnea is defined as lasting for more than 15 to 20 seconds and/or is associated with bradycardia or oxygen desaturation. Prolonged apnea results in short-term disturbances of cerebral hemodynamics and oxygenation, which may negatively affect neurodevelopmental outcome. Treatment involves the administration of caffeine, which has been shown to reduce the incidence of apnea and decrease the risk of bronchopulmonary dysplasia, patent ductus arteriosus, and subsequent development of cerebral palsy (Goryniak et al., 2017).

Sudden Unexpected Infant Death Syndrome

The incidence of **sudden unexpected infant death (SUID)** syndrome fortunately decreased from 120 to 56 deaths per 100,000 live births between 1992 and 2001. While from 2001 to 2008 the rate remained constant, it then declined to 40 deaths per 100,000 live births in 2013. Although the rates have declined significantly, SUID remains the leading cause of post-neonatal (28 days to 1 year of age) mortality in the United States, with over 1,500 infants dying of the disorder in 2013. Ninety percent of SUID cases occur before an infant reaches the age of 6 months, peaking between 1 and 4 months of age (Moon, 2016). SUID occurs more frequently in premature infants than in full-term infants (Moon, 2016). Contrary to earlier beliefs, apnea of prematurity is not a major predisposing factor for SUID. However, because of the increased incidence of SUID among this population, extremely premature infants who are having significant apneic spells in the 2 weeks before discharge may be sent home with an apnea monitor (Committee on Fetus and Newborn, American Academy of Pediatrics, 2003). Although these monitors emit an alarm if the infant stops breathing and alerts the parents to intervene, studies on their use have not

shown effectiveness in reducing the occurrence of SUID. The monitors do, however, provide reassurance to parents and physicians about the status of the infant. Parents of such high-risk infants should be trained in neonatal CPR prior to taking their infant home on an apnea monitor. The monitor is generally not required for more than a few months.

In 1992, in an effort to prevent SUID, the American Academy of Pediatrics' Task Force on Infant Position and SUID began recommending that infants be placed on their back for sleep. In addition, the Task Force recommended that fluffy blankets and toys not be placed in an infant's crib during sleep times and that the home environment be smoke free. These changes have resulted in a more than 50% reduction in the incidence of SUID as noted above (Moon, 2016).

Cardiovascular Problems

The most common cardiovascular problem in LBW infants is a **patent ductus arteriosus (PDA)**. The ductus arteriosus is the fetal vessel that diverts blood flow from the lungs. It normally closes at birth, allowing blood to flow to the lungs and be oxygenated. About 30% of premature infants, and more than 50% of those born weighing less than 1,000 grams, will have a patent (open) ductus arteriosus diagnosed during the first few days of life (Hamrick & Hansmann, 2010). This is especially true in premature infants who have RDS. In these children, a PDA will divert blood from the lungs and further decrease oxygenation to the body and brain, increasing the work of the heart. This can lead to hypoxia, decreased blood flow to specific organs, and heart failure. The presence of a PDA can be detected by echocardiography, a form of ultrasound of the heart. Its management involves medical and supportive measures, including fluid restriction, diuresis (stimulation of urination), and the use of CPAP. If these measures fail, closure is possible using medications such as indomethacin or ibuprofen. In a small percentage of infants, surgical closure is required (Al Nemri, 2014; Noori, 2010).

Gastrointestinal Problems

Although premature infants may be born with a suck-and-swallow response, they are immature and poorly coordinated until approximately 32–34 weeks' gestation. Thus, most premature infants require **nasogastric** (nose to stomach) or **nasojejunal** (nose to small intestine) tube feedings until they can make the transition to oral feeding (Giannì et al., 2017). The nutritional needs of the premature infant are also different from

those of the full-term infant and require the use of specialty formulas. In addition to physiological problems, premature infants are at increased risk for two major gastrointestinal disorders—**necrotizing enterocolitis (NEC)** and **gastroesophageal reflux disease (GERD)**—that can inhibit growth and be life-threatening.

Necrotizing Enterocolitis NEC is the most commonly acquired life-threatening intestinal disease in premature infants. It involves severe injury to a portion of the bowel wall. The exact cause of NEC is unknown, but prematurity appears to be the most common predisposing factor. Approximately 80% of infants with NEC are born at less than 38 weeks' gestation and weigh less than 2,500 grams at birth. Other predisposing factors include fetal distress, premature rupture of membranes, low Apgar scores, and exchange transfusion (where blood is gradually removed from the newborn and replaced with matched adult blood to treat Rh incompatibility). The incidence of NEC is 1 to 2 per 1,000 live births, occurring in 5%–10% of VLBW infants. Although the survival rate of extremely preterm infants has markedly increased, the number of deaths attributed to NEC has been increasing. Mortality rates from NEC range from 15%–30% (Samuels, van de Graaf, de Jonge, Reiss, & Vermeulen 2017).

Medical management of NEC involves withholding feedings, applying nasogastric suction to decrease pressure on the bowel wall, administering antibiotics to fight the suspected underlying infection, and providing intravenous fluids and nutrition to prevent dehydration and weight loss. Although medical treatment can be successful in many infants with NEC, approximately half require surgery to remove the diseased section of the bowel (Sheng et al., 2016). Survivors of NEC may experience a variety of postoperative complications related to the disease, the operation, or treatment measures. Surgery for NEC may involve removal of a large portion of the bowel, leading to decreased absorption of nutrients (Sheng et al., 2016). This is called short bowel syndrome and occurs in up to 11% of postsurgical NEC survivors. It results in chronic diarrhea, malabsorption, nutritional deficiencies, impaired growth, and the long-term need for intravenous nutrition (fats, carbohydrates, and amino acids provided intravenously through a central line).

Gastroesophageal Reflux Disease The immaturity of gastric sphincter muscular control and delayed stomach emptying in premature infants may result in GERD, a syndrome in which the contents of the stomach

are regurgitated back into the **esophagus** (D'Agostino, Passarella, Martin, & Lorch, 2016). Infants with severe GERD are at increased risk for vomiting and **aspiration pneumonia** (a lung infection precipitated by the **aspiration** of food into the lung), which may be worsened by nasogastric tube feedings. Signs of GERD include refusal of oral feeding, apnea, irritability, and back arching. Treatment is targeted toward special positioning techniques and medications (see Chapter 10).

Retinopathy of Prematurity

Impairments in retinal vascular development after preterm birth lead to **retinopathy of prematurity (ROP)**, formerly called *retrolental fibroplasia*. The highest risk infants are those born at less than 28 weeks gestational age and weighing less than 1 kilogram at birth (Chan-Ling, Gole, Quinn, Adamson & Darlow, 2017). A pediatric ophthalmologist should perform an examination for early detection of ROP at 4–6 weeks after birth or at 32–33 weeks' gestation (whichever comes first). Follow-up examinations should be done until retinal vascularization is complete, usually around term gestation (see Chapter 7). Preventive therapy with early human milk feeding and vitamins A and E supplements may decrease the severity of ROP in susceptible infants (Porcelli & Weaver, 2010). Severe ROP is treated by laser to prevent permanent retinal detachment.

Immunologic Problems

The premature infant is born with an immature immune system. As a result, the infant is at increased risk for infection in the first months of life (Wilińska, Warakomska, Głuszcak-Idziakowska, & Jackowska, 2016). Generalized bacterial and fungal infections, occurring in approximately 30% of extremely premature infants, are major life-threatening illnesses and can lead to a poor neurodevelopmental outcome (Wilińska et al., 2016). Premature infants who remain in the hospital for prolonged periods should receive routine immunizations based on their chronological age.

Other Physiologic Impairments

Premature infants are at increased risk for many of the same transient physiological impairments that occur in full-term infants. These include hyperbilirubinemia, anemia, hypoglycemia, hyperglycemia, hypocalcemia, and hypothermia. These problems place the premature infant at increased risk for brain damage.

Acidosis and hypoxia, resulting from inadequate respiration, can increase the permeability of the blood–brain barrier to bilirubin, making preterm infants more susceptible to **kernicterus**. In kernicterus, there is the deposition of bilirubin pigment in the brain, leading to athetoid cerebral palsy, hearing loss, vision problems, and/or intellectual disability. Thus, the bilirubin level that is used to determine whether phototherapy or an exchange transfusion should be performed is lower for the preterm infant than for the full-term infant (Maisels, Watchko, Bhutani, & Stevenson, 2012). **Glucose** and **electrolyte** instability are also common in premature infants, especially the ELBW infant.

Anemia usually is more of a problem for the premature infant than for the full-term infant because it decreases the oxygen-carrying capacity of the red blood cells and can lead to hypoxic–ischemic brain damage. Preterm infants, especially ELBW infants, are exposed to frequent blood draws as part of their routine care in the NICU, which lowers their red blood count. These infants develop anemia of prematurity due to inadequate production of erythropoietin, which normally stimulates the bone marrow to produce red blood cells. In severe cases, anemia of prematurity is corrected with blood transfusion and/or treatment with erythropoietin (Bishara & Ohls, 2009). In recent years, revised transfusion guidelines have significantly reduced the use of transfusions in the LBW premature infant and the need for erythropoietin in ELBW infants (Bishara & Ohls, 2009).

Finally, premature infants often have a transient deficiency of thyroid hormone production. In severe cases, this condition may be associated with neurodevelopmental impairments. However, in most cases, the hypothyroidism resolves without the need for thyroid hormone replacement therapy and does not negatively impact long-term outcomes (van Wassenaer-Leemhuis et al., 2014).

MEDICAL AND DEVELOPMENTAL CARE OF LOW BIRTH WEIGHT INFANTS

The best treatment for LBW infants is prevention of preterm births. This starts with identifying women at risk and providing them with education and prenatal health care. In addition, detecting preterm labor early and using labor-arresting agents and antenatal steroid therapy are very effective methods for preventing neonatal mortality and morbidity (Roberts et al., 2017). Prenatal care has improved appreciably since the 1970s, but the incidence of preterm delivery remains high. Preterm and SGA infants are best managed and cared

for in high-risk obstetrical centers/children's hospitals with NICUs.

The increased survival rate of preterm infants has the potential for increasing the number of children with adverse neurodevelopmental outcome. Fortunately, since the year 2000 neurodevelopmental impairments have actually decreased among ELBW infants. A variety of perinatal and neonatal factors have been associated with this improved outcome, including increased antenatal steroid use and cesarean section delivery. These interventions have resulted in decreased risk of sepsis and less severe cranial ultrasound abnormalities. There has, however, been no change in the rate of chronic lung disease despite the postnatal use of steroids to stimulate surfactant production (Pierrat et al., 2017).

As survival rates of preterm infants have improved, the focus of care is now on creating the optimal environment within the NICU for the premature infant to develop. Traditional NICU care has focused on medical protocols and procedures. A newer approach uses a more relationship-based, individualized, developmentally supportive model. This approach recognizes that the usual NICU setting is not optimal for the premature infant's developmental progress. Typical NICU care has involved the infant experiencing prolonged diffuse sleep states, unattended crying, a high ambient noise level, bright ambient light, a lack of opportunity for sucking, and poorly timed social and caregiving interactions.

The newer approach seeks to observe the infant's behavior and respond to it appropriately by providing individualized neurodevelopmental care and actively involving the parents in their infant's care (McAnulty et al., 2013). This involves documenting infant behavior, including breathing pattern, color fluctuations, startles, posture, and sleep state. Caregiving suggestions and environmental modifications are then based on these observations. One of the techniques involving the parent is termed **kangaroo care**. Once the premature infant has reached physiologic stability and does not require major respiratory support, he or she is placed on the parent's chest. Kangaroo care (parent–infant skin-to-skin contact) has been shown to improve preterm growth, decrease hospital-acquired infections, and possibly shorten hospital length of stay (Head, 2014). These developmental approaches have been associated with improved functioning of the neonate in the NICU, including the infant having a reduced number of apnea events, faster weight gain, improved oxygenation, motor maturity, and behavioral state organization. Research is ongoing to determine whether this approach carries long-term benefits.

In addition to environmental modifications that support development, early intervention services can be provided even before the child is discharged from the NICU. Once the infant is medically stable, a team consisting of a physical and/or occupational therapist, speech pathologist, developmental psychologist, and/or developmental pediatrician should evaluate the child. Care plans should be developed to provide parents with training regarding the ongoing developmental needs of the child after discharge (see Box 5.2). This may also include referral to an early intervention program in the community (see Chapter 31).

SURVIVAL OF LOW BIRTH WEIGHT INFANTS

Advances in medical technology in neonatal intensive care and their application to the premature infant have been very successful in reducing mortality. Since 1960, survival of LBW infants has increased from 50% to more than 90% (Table 5.1). This improvement has been even more remarkable in ELBW and micropremie infants. ELBW infants who survive the first few days of extrauterine life have a far better chance of long-term survival. Although the overall survival for infants with a birth weight of less than 500 grams was only 8%, those who lived through the first 3 days of life had up to a 50% chance of survival. Infants in the 500- to 749-gram birth weight category had an overall survival rate of 50%. That increased to 70% if they survived through the third day and 80% by the end of the first week of life (Mohamed, Nada, & Aly, 2010). A more recent study has shown that infants who were born between 2005–2011 at 22 to 24 weeks' gestation had a significantly lower mortality compared with those born from 1998–2004 (42% versus 55%). Neurodevelopmental

Table 5.1. Improvement in survival rates of premature infants

Birth weight (g)	Survival (%)		
	1960	1990	2004
500–750	10	30	50
750–1,000	20	70	85
1000–1,500	30	90	98
1500–2,000	50	90	> 98

impairment among surviving infants also declined from 68% to 47% (Younge et al., 2016).

CARE AFTER DISCHARGE FROM THE HOSPITAL

The medical cost of the hospitalization and care of preterm infants who require prolonged NICU stays is extraordinarily high, often measured in hundreds of thousands of dollars. Length of stay is a major factor in this cost. As a result, many centers are developing care pathways that allow the medical team to consider earlier discharge than previously practiced for stable premature infants. This new approach needs to be monitored closely to ensure that earlier discharge does not compromise the health of infants and result in an increased risk of readmission to the hospital for treatment of medical complications.

Clinical criteria for discharging preterm LBW infants are based on the achievement of sufficient weight and maturity of body organ function to ensure medical stability and continued growth in a home environment. This generally involves the infant being

BOX 5.2 INTERDISCIPLINARY CARE

Specialty Services Required At or After Discharge

Many premature infants may still require specialty services at or after time of discharge to home, which may include some or all of the following services:

- Occupational therapy
- Physical therapy
- Speech therapy
- Ophthalmology follow-ups for retinopathy of prematurity
- Pulmonary follow-ups if discharged on home oxygen and with an apnea monitor
- Gastroenterology and nutritional follow-ups
- Neurodevelopmental follow-ups

able to feed well by mouth, continue to gain weight, maintain a stable body temperature outside of an isolette, and no longer experience episodes of apnea and bradycardia. Most preterm LBW infants meet these eligibility criteria at a postconceptional age of 35–37 weeks. For ELBW infants, discharge at a postconceptional age of 37–42 weeks is a more realistic goal (Jefferies, 2014). At the time of discharge, most infants weigh between 1,800 and 2,000 grams (4 to 4½ pounds).

When premature infants are discharged, parents may be faced with the stress and difficulty of caring for an infant with many special needs. The prolonged duration of hospitalization and separation from parents also may have interfered with the usual parent–infant bonding. Premature infants may be more irritable, cry more often, and have poorer sleep–wake cycles compared with full-term infants. Because of an immature sucking pattern, they often require more frequent feedings. Specialized formula and/or breast milk supplementation with a human milk fortifier are now available to meet the caloric needs of premature infants post discharge.

As a result of these stresses, it is important to provide adequate support for the family after discharge, including close medical supervision and home-care visits by nursing and/or social work staff (Aydon, Hauck, Murdoch, Siu, & Sharp, 2017). Parental education regarding the needs of a growing preterm infant is extremely important. Ideally, the infant should be discharged to a home environment that is free of smoke and any other potential respiratory irritants such as kerosene heaters, fresh paint, and people with respiratory-related viral illness. Each of these factors plays a crucial role in causing subsequent respiratory illnesses or in exacerbating the underlying lung disease.

To prepare premature infants and their parents for the infant's discharge, most centers provide rooming-in services for the parents. This allows the parents to take over the care of their infant under the supervision of the NICU staff members who determine whether there are unforeseen problems. The parents also learn about the care of their infant, thereby reducing the stress and anxiety of taking a preterm infant home (Broedsgaard & Wagner, 2005).

EARLY INTERVENTION PROGRAMS

Early intervention programs have been shown to benefit the neurodevelopment of most premature infants through 3–5 years of age, although longer-term effects are still debated (Koldewijn et al., 2010; Spittle, Orton, Anderson, Boyd, & Doyle, 2015). In a study of children with birth weights less than 2 kilograms, there was no

significant difference in Mental Developmental Index scores at 3 years of age (after adjustment for maternal education) between children who receive early intervention services and those who do not; however, there was a statistically significant benefit shown via full-scale IQ scores at 5 years. With respect to motor outcomes, there were no differences between the groups receiving services and those not receiving services (Nordhov et al., 2010).

These programs should start for many premature infants prior to discharge from the hospital and continue until the child reaches 3 years corrected age. Corrected age is calculated by first determining how premature the child was in weeks (subtract the child's gestational age at birth from 40 weeks); then that number is subtracted from the child's current chronological age. For example, a child born at 28 weeks was 12 weeks early. To obtain the corrected age, 12 weeks (i.e., 3 months) should be subtracted from the child's age. The corrected age for an 8 month old born at 28 weeks' gestation is therefore 5 months. This correction is generally done until 12–24 months chronological age.

The intervention strategy incorporates group meetings for parents, home visits, and after 24 months' chronological age, attendance at a multidisciplinary child development center with a low teacher-to-infant ratio (i.e., one teacher to three or four infants; see Chapter 31). It is important to recognize that even after completion of the early intervention program, many of these children continue to need special education services, including speech-language therapy, physical and/or occupational therapy, special education, behavior therapy, and treatment of emotional problems. If these children do not receive these services, the benefits of early intervention may be lost over time (Guralnick, 2012).

NEURODEVELOPMENTAL OUTCOME

Most infants born prematurely can be viewed during infancy as developing at a typical rate when their corrected or adjusted age is determined from their expected date of birth rather than from their actual birth date. There are, however, differences between full-term and preterm infants even when gestational age is taken into account. Although few premature infants develop cerebral palsy, in terms of motor skills, they often lack the smooth, rhythmic movement patterns of full-term infants. Devices such as walkers and jumpers should be avoided because they encourage the infant to stand on tiptoe and walk in an atypical pattern. In later infancy, visual-motor tasks that require the planned use of arms and hands are also more difficult. Coordinating reach and grasp, scooping with a

spoon, managing a standard cup, copying block constructions, and completing crayon/paper tasks can be more difficult (Sripada et al., 2015).

By school age, the developmental status of preterm children who had birth weights above 1,500 grams is not very different from full-term infants. Late-preterm infants born at 34–36 weeks' gestational age who are otherwise healthy seem to have no real burdens regarding cognition, achievement, behavior, and socioemotional development throughout childhood (Gurka, LoCasale-Crouch, & Blackman, 2010). Children with birth weights below 1,500 grams and less than 32 weeks' gestation, however, have an increased risk for developmental disabilities. School-age children who were born very preterm or had ELBW are at greater risk of developing executive function deficits (seen in children with attention-deficit/hyperactivity disorder [ADHD], learning disabilities, and autism) and at greater risk of requiring ongoing neuropsychological follow-up through middle childhood (de Kieviet, van Elburg, Lafeber, & Oosterlaan, 2012; Eryigit Madzwamuse, Baumann, Jaekel, Bartmann, & Wolke, 2015; Hutchinson, De Luca, Doyle, Roberts, & Anderson 2013; Johnson et al., 2015; Joseph et al., 2017; Peralta-Carcelen et al., 2017).

In terms of behavior issues, children born prematurely are at risk for lower levels of social competence, and they are often less adaptable, less regular in their habits, less persistent, and more withdrawn. ADHD is also more common in this group (de Kieviet et al., 2012). Signs of ADHD may appear as early as 2 years of age, with hyperactivity and difficulty following verbal directions or listening to a story (see Chapter 19). In addition, there may be behavior differences such as sleep disturbances, feeding difficulties, tantrums, and/or resistance to limit setting (Johnson et al., 2015). Learning differences may be anticipated in children whose language is delayed and who demonstrate poor visual-motor coordination (Sripada et al., 2015; also see Chapter 20). Family factors have also been found to be strong predictors of future school performance (Garfield et al., 2017). Optimal school outcome has been significantly associated with increased parental education, child rearing by two parents, stability in family composition, socioeconomic status, and geographic residence.

Major developmental disabilities have been found in about one quarter of children with a birth weight less than 1,000 grams (i.e., ELBW infants and micropreemies). This includes cerebral palsy; hearing impairment; visual impairment; and, at 18–22 months' corrected age, a mean mental developmental index of less than 85 (Hintz, Newman, & Vohr, 2016). Although cerebral palsy, especially spastic diplegia, is not uncommon in children who were VLBW, many "outgrow"

this diagnosis by school age and simply appear to be less coordinated or to have motor-associated learning difficulties.

In terms of predicting future neurodevelopmental disabilities, in one study, 30%–40% of ELBW infants with a normal cranial ultrasound were later found to have either cerebral palsy or intellectual disability (Hintz et al., 2016). A neonatal brain MRI at corrected term gestation and/or before discharge appears to be a better predictor of severe neurodevelopmental disorders (El-Dib et al., 2010; Hintz et al., 2016). In one study, sensorineural hearing impairments were correlated with neonatal sepsis and jaundice; neurological, developmental, neurosensory, and functional morbidities increased with a decreasing birth weight; and, overall, males were more at risk for disabilities than were females. In addition, infants born SGA are at increased risk for lower cognitive performance as young adults. However, this lower capacity is not considered sufficiently severe to affect their educational level or social adjustment (Yi, Yi, & Hwang, 2016).

SUMMARY

- When compared with full-term infants, LBW infants—in particular, VLBW infants/micropreemies—are at greater risk in the newborn period for many problems that may lead to long-term complications.
- Physiologic immaturity of organ systems often leads to RDS, hyperbilirubinemia, hypoglycemia, and hypocalcemia.
- Most of these infants recover from these transient complications without major long-term sequelae.
- Other problems, such as IVH, PVL, sepsis, and persistent apnea and bradycardia, are associated with poor neurodevelopmental outcome.
- With increased public awareness, improved prenatal care, advanced neonatal intensive care, increased parent involvement in the NICU, and access to early intervention services, the outcome of premature and SGA infants is likely to continue to improve.

PART II

The Child's Body

Physiology

CHAPTER 6

Fetal Development

Nickie N. Andescavage

Upon completion of this chapter, the reader will

- Explain the fundamental principles of fetal development from conception to term birth
- Describe the complex interplay of maternal-placental-fetal health during gestation
- Identify the various mechanisms that can disrupt normal fetal development

A single egg joins a single sperm cell, and 9 months later an infant is born. When all goes well, from those two cells will come 10 fingers and toes, one heart, two lungs, a brain, and other normally functioning body organs. Embryonic/fetal life allows for the protected development of the fertilized egg into a complex, multi-organ human through a highly structured pattern of development. However, deviations from normal development can have a significant and long-lasting impact. Early severe **anomalies** (congenital abnormalities) in the developmental sequence can result in a miscarriage, whereas more subtle anomalies may go undetected until after birth when functional impairment is noted.

This chapter provides an overview of normal human development. It describes the critical steps that take place in development as well as periods of vulnerability when body organs are particularly susceptible to long-lasting consequences if the normal developmental sequence is disrupted. It also explains the concept of the fetal origin of certain adult diseases, including heart disease, diabetes, cancer, and psychiatric-neurobehavioral disorders (Calkins & Devaskar, 2011;

Fall & Osmond, 2013). Chapter 1 and Chapter 2 in this volume describe the genetic, biologic, and environmental influences that contribute to specific developmental disabilities; this chapter emphasizes how these and other factors influence fetal health and the long-term impact on neurodevelopment. It also provides an overview of the evaluation of fetal development, diagnostic considerations, and management strategies.

■ ■ ■ CASE STUDY

Jane is a 33-year-old woman pregnant with her first child and is currently in her second trimester. She is generally healthy, although she had significant nausea and vomiting during her first trimester that was treated with antiemetic medication. As the morning sickness has now subsided, her only current medication is a daily prenatal vitamin. Her family history is notable for hypertension (mother), type 2 diabetes (father), and a sister who had two miscarriages prior to the delivery of a healthy boy. Jane's work for an international nonprofit organization involves frequent travel to Central and South America. She is a nonsmoker and describes herself as a social

drinker (1-2 glasses of wine per week). She immediately stopped drinking once she learned she was pregnant at 6 weeks' gestation. During a routine prenatal visit at 20 weeks' gestation, Jane's obstetrician noted that her uterus measured smaller than expected and arranged for a fetal imaging procedure to be performed. Fetal measurements on ultrasound revealed asymmetric (unequal in size/shape) fetal growth, and she was referred to a maternal-fetal medicine specialist for the further evaluation of her small-for-dates fetus.

Thought Questions:

What can affect the fetus and cause subsequent neurodevelopmental disabilities? What can be done to optimize fetal neurodevelopment?

OVERVIEW OF KEY ANATOMIC STRUCTURES

Early human development requires the close and interdependent interaction of the maternal-fetal-placental unit. By the end of the first trimester, the placenta is a mature, established organ that nourishes and protects the developing fetus through the close physical approximation of the maternal and fetal circulations (Figure 6.1). Blood from the maternal circulation reaches the placenta through the uterine arteries and **perfuses** (pushes blood to) the uterine wall. The mother's endometrial arteries then send the blood into the **intervillous space** (the space between the villi containing the vessels of the mother and embryo). The intervillous space surrounds and bathes the fetal vessels,

Figure 6.1. Placenta and maternal-fetal circulation. Blood from the maternal circulation reaches the placenta through the uterine arteries and perfuses the uterine wall. The endometrial arteries send blood into the intervillous space; the intervillous space, in turn, surrounds and bathes the fetal vessels, allowing for the transfer of gases, nutrients, and waste between the fetus and mother.

promoting the transfer of gases (oxygen and carbon dioxide), nutrients, and waste between the fetus and mother.

The fetal circulation differs from the adult circulation in several important ways. The most nutrient-rich blood exits the placenta via the umbilical vein and returns to the fetus where two transient fetal structures (the **ductus venosus** and the **foramen ovale**) shunt this blood to the ascending aorta and thereby to the developing brain (Figure 6.2). These mechanisms allow for the most oxygenated and nutrient-dense blood to preferentially perfuse the developing brain. Any disruption in the maternal-placental-fetal circulation can have long-lasting consequences for the neurodevelopment of the fetus.

HUMAN DEVELOPMENT

Human development follows a highly ordered sequence of events and requires a consistent reference starting point. Embryologists use **postconceptional age** (PCA) as a metric for development. PCA dates the onset of human development from the presumed date of ovulation (when fertilization occurs). Within this context, intrauterine development is divided into two phases, the **embryotic period** (the first 8 postconceptional weeks) and the **fetal period** (from 9 weeks until birth).

Clinicians, on the other hand, use **gestational age** (GA) in weeks as a metric for embryonic-fetal

Figure 6.2. Fetal circulation: The foramen ovale and patent (open) ductus arteriosus allow the blood flow to bypass the unexpanded lungs.

development. The GA is measured from the first day of the last menstrual period, that is, 2 weeks earlier than PCA. Using GA, the intrauterine period is divided into trimesters. The first trimester extends to 12 weeks GA, the second from 13 to 28 weeks GA, and the third trimester from 29 weeks until term (40 weeks GA).

This section describes the timeline of typical human development during the embryonic and fetal periods (Figure 6.3). This information will lay the foundation to understand the next sections, which describe how deviations from developmental norms can contribute to neurodevelopmental disabilities.

The Embryonic Period

During the embryonic period, the individual body organs are formed. The heart is the first organ to develop, with a primitive heart tube and developing circulatory system beginning to function around 6 weeks GA. At this time, the **rostral** end of the neural tube (destined to become the fetal head) begins to differentiate into sections that will form the major components of the brain—the forebrain, midbrain, and hindbrain (Figure 6.4)—along with the basic components of the spinal cord.

The embryonic period is divided into three stages: germinal, gastrulation, and neurulation. Genetic and environmental induced defects during this period most commonly lead to miscarriage. However, some affected embryos survive and are born with disorders that can

Figure 6.4. Development of the fetal brain. This is a side view illustrating the increasing complexity of the brain over time. The forebrain, or prosencephalon, develops into the cerebral hemispheres; the midbrain, or mesencephalon, develops into the brainstem; and the hindbrain, or rhombencephalon, develops into the cerebellum, pons, and medulla. Although all brain structures are formed by 4 months, the brain grows greatly in size and complexity during the final months of prenatal development.

be associated with developmental disabilities. These disorders include chromosomal disorders (e.g., Down syndrome), single-gene disorders (e.g., neurofibromatosis), toxic exposures (e.g., fetal alcohol syndrome), and congenital malformations (e.g., neural tube defects).

Figure 6.3. Embryogenesis and fetal development. (From Moore, K. L., & Persaud, T. V. N. [1993]. *Before we are born: Essentials of embryology and birth defects* [4th ed., inside back cover]. Philadelphia, PA: W. B. Saunders; adapted by permission.) The majority of major malformations results from deviations of normal embryonic development and coincide with the emergence of each major organ system. Insults to the developing fetus, after the basic structural elements of organ formation, typically result in functional defects or minor malformations.

Germinal Stage The **germinal stage** of human development occurs during the period between fertilization and implantation of the developing embryo (Figure 6.5). It begins with the fusion of the egg and sperm, resulting in a single-celled **zygote**, the fertilized egg cell. The zygote divides into two cells; then the two cells divide into four, four cells to eight, and so on. These dividing cells are known as **blastomeres** and create a spherical group of cells known as the **morula**. Within a few days of fertilization, these cells develop into two distinct cell types in a process known as cellular differentiation. The outer layer of cells becomes **trophoblast** cells, which will go on to develop the placenta; the inner mass cells or **embryoblasts** go on to form the human embryo.

Gastrulation Stage During the **gastrulation stage**, the developing embryo organizes into three layers of cells, with distinctive head-to-tail, front-to-back, and left-right differentiation. It is during this period that the forerunners of the structures and organs that make up an infant begin to develop. The outermost layer, or

ectoderm, will give rise to the skin, nervous system, eyes, inner ear, and connective tissues. **Neural crest** cells are a transient group of cells that arise from the ectodermal layer and become the neurons, glia, and skin cells.

Abnormalities in the differentiation of neural crest cells are believed to underlie **neurocutaneous syndromes**, a collection of conditions that affect both skin and brain and lead to developmental disabilities. The most common of these disorders are neurofibromatosis, Sturge-Weber disease, and tuberous sclerosis. The middle layer, or **mesoderm**, will become the heart and circulatory system, bones, muscles, and kidneys. The inner layer, or **endoderm**, will develop into the lungs, intestine, thyroid, pancreas, and bladder.

Neurulation Stage In the **neurulation stage**, the disc-like structure of the developing embryo folds over to form the neural tube, which will eventually form the central nervous system, brain, and spinal cord (Figure 6.6). *Primary neurulation* is the process by which the flat neural plate develops a midline groove, the edges of which fold over, converge, and fuse. *Secondary neurulation* is a series of events that result in the creation of the neural tube by hollowing out its center.

Defects in primary neurulation result in congenital malformations known as neural tube defects, including spina bifida (**meningomyelocele**) and **encephalocele**. Defects in secondary neurulation lead to the **caudal regression syndrome** that can result in major malformations of the lower vertebrae, pelvis, and spine.

The Fetal Period

Although all major organ systems have formed by the end of the embryonic period, they are not fully functional. For the remainder of gestation, termed the fetal

Figure 6.5. Germinal stage of fetal development. This figure shows the germinal stage of human development from fertilization to implantation of the blastocyst, or early embryo. The ovum (egg) is dropped from the ovary into the fallopian tube, where it is fertilized by a sperm. The fertilized egg begins dividing as it travels toward the uterus. Two distinct cell types begin to emerge—the outer layer (trophoblast) and inner cells (embryoblasts)—as it enters the uterine cavity and implants into the maternal wall.

Figure 6.6. Neurulation. Development of the central nervous system during the first month of the embryonic period. This is a longitudinal view showing the gradual closure of the neural tube to form the spinal column and the rounding up of the head region to form the primitive brain.

period, the individual organs, organ systems, and body will grow and develop. As this text addresses neurodevelopmental disabilities, this section focuses on the structural development of the fetal brain and what can go wrong, particularly in the cerebrum and cerebellum. Cerebral development can be divided into four periods: 1) neural proliferation, 2) neuronal migration, 3) cortical organization and synapse formation, and 4) myelination.

Neural Proliferation Period Neural proliferation occurs during a sustained period of vigorous cellular division that peaks between 6 and 27 weeks GA. This period gives rise to precursors of the **neuronal** (grey matter) and **glial** (white matter) cell populations of the brain. There are two early populations of nerve cells: the dorsal neuroepithelium, which forms the neuronal population and pathways important for cognition, motivation, and memory, and the ventral neuroepithelium, which gives rise to the future interneuronal population that produces the neurotransmitter gamma aminobutyric acid (GABA). During early brain development, GABA exerts an excitatory function but later switches to become the principal inhibitory neurotransmitter. Maternal ingestion of antiepileptic medication (e.g., valproate) during this period can have teratogenic effects (causing anomalies) on the fetus through its impact on GABA.

The rapidly growing periventricular regions of the brain are particularly susceptible to injury during this time from viral infections (e.g., **cytomegalovirus [CMV]**) and exposure to radiation or alcohol (see Chapter 2). This can result in **microcephaly** (abnormally small head) and developmental disturbances of other body organs (Volpe, 2008).

Neuronal Migration Period After neuronal proliferation, the neurons start to migrate out toward the surface of the brain in successive waves beginning at 12 weeks GA and ending by 20 weeks GA. This results in the development of the folds (**gyri**) and grooves (**sulci**) that give the typically developed brain a walnut-like appearance and increase its surface area and complexity (see Figure 6.4).

Disturbances in cell signaling and neuronal migration can result in a variety of structural anomalies generally referred to as neuronal migration disorders, such as **lissencephaly** (a “smooth” brain with a lack of gyri and sulci) and **polymicrogyria** (too many small folds). In addition, disturbances in early neuronal migration may play a role in the subsequent development of complex partial seizures (see Chapter 22) and autism (see Chapter 18; Bystron, Blakemore, & Rakic, 2008; Zhao et al., 2006).

The **subplate zone**, just under the developing cortex, is a transient area that plays a critical role in the development of numerous cortical pathways and connections. These act as the relay zone and communication hub for higher cortical processing (Kostovic & Judas, 2010). Abnormalities in subplate development and function have been associated with several neuropsychiatric conditions including epilepsy (see Chapter 22), schizophrenia, and autism (see Chapter 18; Hoerder-Suabedissen & Molnár, 2015).

Cortical Organization and Synapse Formation

A **synapse** is the point at which an impulse passes from one neuron to another, resulting in neural activation or communication. Neural activation occurs early in development through gene activation and growth factor support, which lead to the formation of synapses. This can result in the major overproduction of synapses, requiring “pruning back” or reorganization during subsequent phases of brain development. This pruning activity does not occur properly in certain conditions such as Down syndrome and fragile X syndrome (see Chapter 15). Inadequate pruning has also been implicated in the development of attention-deficit/hyperactivity disorder (ADHD) and learning disabilities (see Chapters 19 and 20; Cellot & Cherubini, 2013; Naaijen et al., 2017).

The next phase of cortical organization involves the development and refinement of synapses. Synaptic communication allows for the establishment of the complex behavioral actions necessary in postnatal life. Rett syndrome and fragile X syndrome are genetic disorders that result from abnormalities in neuronal maturation and synaptic function and result in cognitive and behavioral disturbances (Banerjee, Castro, & Sur, 2012).

Myelination The efficacy of neural connectivity for both cognition and movement depends not only on the successful conduction of electrical impulses across synapses, but also on the speed and coordination of these transmissions. This process is facilitated and accelerated by axonal **myelination**. During myelination, **oligodendrocytes** (a type of neuronal support cell) attach and wrap myelin along the length of a neuronal axon. The sheath of myelin from the oligodendrocytes serves to insulate the neuron and facilitate the conduction of signals between cells.

During fetal development, myelination starts in the spinal cord and brainstem and proceeds upward toward the cerebrum. At 40 weeks’ gestation (the time of a typical birth), myelination has only advanced into the brainstem, cerebellum, and **internal capsule** (white

matter near the thalamus). Myelination of the cerebral white matter occurs relatively late, reaching its peak during the first year of postnatal life. Because of the prolonged period of myelination, early injury to oligodendrocytes and their progenitors may not result in clinical symptoms until well after birth. Oligodendrocytes and their progenitors are particularly vulnerable to infection, inflammation, and **hypoxia-ischemia** (lack of adequate oxygenation or blood circulation). Such events during the latter part of fetal life or in the premature neonate can permanently injure the developing oligodendrocytes and may be responsible for certain forms of cerebral palsy (see Chapter 21; Back et al., 2001).

The Developing Cerebellum Extensive cerebellar development during intrauterine life exposes it to a prolonged period of risk for injury and maldevelopment. In addition, cerebellar **hypoplasia** (undergrowth) has been associated with certain genetic disorders, including Dandy-Walker syndrome, Werdnig-Hoffman syndrome, and Walker-Warburg syndrome. Increasingly, injury or maldevelopment of the cerebellum is recognized as contributing to significant motor and nonmotor functions, including cognition, language, and behavioral regulation, especially in premature neonates (Limperopoulos et al., 2007).

PLACENTAL DEVELOPMENT AND FUNCTION

The human placenta is a temporary, yet critical organ necessary for human development. Connecting the fetus to the maternal uterine wall, the placenta allows for gas and nutrient exchange between the maternal and fetal circulations, as well as for the elimination of waste and toxins. It also performs critical immune and endocrine functions. Although the placenta allows for the close approximation of maternal and fetal circulations, the placental barrier maintains each as a distinct compartment (see Figure 6.1).

Nutrition and Excretion

One of the main functions of the placenta is the active and passive transfer of nutrients from the maternal to the fetal circulation. In return, the placenta allows for the excretion of toxins and waste from the fetal to the maternal circulation, where it can be further processed and excreted by the mother. Gases, including oxygen and carbon dioxide, can readily **diffuse** (passively move along a concentration gradient) across the placental barrier. Similarly, small molecules and electrolytes (like sodium and potassium) can cross the placental barrier

via diffusion. Transporters on the placental membrane also allow for active diffusion against concentration gradients and for the engulfment and transport of larger proteins and nutrients (Walker et al., 2017).

Immunity

Immune cells from the placenta release **cytokines** (substances such as interferon, interleukin, and growth factors) into the maternal circulation that activate the maternal immune system. This activation increases antibody and immunoglobulin production in the mother. It also renders the fetus more immunocompetent and leads to the release of cytokines that promote placental implantation and growth. In addition, many maternal antibodies cross the placenta during the second half of pregnancy and provide passive immunity to the newborn for several months after birth. This helps protect the infant from developing infections and immunologic disorders (Malek, 2013). The placenta's immunologic features also protect the fetus from being physically rejected by the maternal immune system as would normally happen to a "foreign body."

Endocrine Function

The placenta is responsible for the production of numerous hormones throughout gestation that are necessary for normal maternal, fetal, and placental function. Immediately after implantation, the placenta produces human chorionic gonadotropin, progesterone, and estrogens—all of which facilitate normal implantation and development of the blastocyst. Hormones that increase later in gestation promote **angiogenesis** (growth of blood vessels) as well as general fetal and placental growth. In addition, the placenta produces many neurosteroids and neurosteroid precursors that are thought to be protective of the developing brain (Costa, 2016; Hirst, Palliser, Yates, Yawno, & Walker, 2008).

MATERNAL, FETAL, AND PLACENTAL ORIGINS OF DEVELOPMENTAL DISORDERS

As described previously, the steps necessary for a successful pregnancy and typical human development require a complex interplay of fetal, maternal, and placental factors. Beyond the genetic make-up of the fetus, it is now known that the early intrauterine environment greatly influences human development. Recognizing that there is significant overlap of maternal, placental, and fetal contributions to fetal health, this section describes general periods of vulnerability,

focusing on the developing brain and the multifactorial mechanisms of disrupted brain development.

Preconception Period

In many ways, fetal vulnerability to developmental disabilities begins even prior to conception. These risks include parental age, health, and nutrition. Advanced maternal age is associated with impaired egg quality; rates of **aneuploidy** (the genetic mechanism responsible for trisomy 21, also called Down syndrome) increase up to 50% in older mothers (see Chapter 1). In addition, maternal age is believed to impact epigenetic modifications (where genes are turned on and off) that may further diminish egg quality. Advanced paternal age is also believed to impact sperm quality as well as increase the amount of DNA damage/mutation in sperm. In contrast to chromosomal anomalies associated with advanced maternal age, advanced paternal age is more commonly associated with single gene mutations resulting in autosomal dominant disorders (see Chapter 1). There have been some population-based cohort studies that suggest an association between advanced paternal age and the development of neuropsychiatric disease (e.g., schizophrenia and autism), presumably mediated by cumulative DNA damage to key genetic sites. Parental exposure to environmental toxins, such as mercury or lead, is an additional concern in the development of birth defects and low birth weight infants (Bray, Gunnell, & Davey Smith, 2006; Ge, Schatten, Zhang, & Sun, 2015; Sadler, 2015).

Optimizing maternal health is important during the period prior to conception as well as during pregnancy. Many chronic diseases that impact maternal cardiovascular function (e.g., diabetes mellitus, hypertension, and obesity) can compromise uterine blood flow and uterine-placental function. This placental dysfunction results in substandard nutrient transfer, chronic fetal hypoxia, fetal growth restriction, and premature birth. These conditions are well-described risk factors for brain injury and developmental disabilities. Maternal hyperglycemia due to poorly controlled diabetes mellitus can be teratogenic, particularly early in pregnancy. Using the preconception period to stabilize chronic maternal disease provides direct benefit by improving maternal cardiovascular status, glycemic index, and limiting or eliminating maternal medications that also may be teratogenic (Shannon, Alberg, Nacul, & Pashayan, 2014).

Preconception is also the time to improve maternal nutrition. Low pre-pregnancy weight is associated with premature birth, while folic acid and iron supplementation (if there is maternal iron-deficient anemia) are associated with improved fetal growth, decreasing the

risk of fetal growth restriction, and low birth weight infants (De-Regil, Fernandez-Gaxiola, Dowswell, & Pena-Rosas, 2010; Dean, Lassi, Imam, & Bhutta, 2014; Hodgetts, Morris, Francis, Gardosi, & Ismail, 2015). Folic acid supplementation prior to conception and throughout pregnancy also has been estimated to reduce the risk for neural tube defects by 70% as well as congenital heart disease (Tur-Torres, Garrido-Gimenez, & Alijotas-Reig, 2017; Viswanathan et al., 2017). Multivitamin supplements help decrease other teratogenic risks.

Embryonic Period

Typically, deviations from normal development during the embryonic period result in major structural **malformations** (the complete or partial absence of a body structure or alteration of its normal configuration). It is estimated that up to one half of all conceptions result in miscarriage (often referred to as spontaneous abortions), with up to 80% occurring during the embryonic period. Of all miscarriages, approximately half occur because of genetic abnormalities, particularly chromosomal anomalies. The other half result from external factors affecting the mother, fetus, or placenta as discussed earlier (Petracchi, Colaci, Igarzabal, & Gadow, 2009).

The initial risk to the embryo is the implantation of the blastocyst during the germinal period. Antigen presentation from the developing embryo to the mother during implantation is the trigger to activate the maternal immune system and shift from a primarily cell-mediated to antibody-mediated immunity. If this shift does not occur, the embryo will be rejected, resulting in pregnancy loss. Another problem is if implantation occurs outside the uterus. This results in an ectopic pregnancy, which most commonly leads to embryonic death around the second month of gestation. Even the location of embryonic implantation within the uterus can become problematic. Optimal sites for implantation are along the **anterior** (front) or **posterior** (back) wall of the uterus. Implantation near the cervix can cause **placenta previa**, in which the placenta overlies the cervix and may result in bleeding or premature delivery.

Specific genetic mutations affecting formation of the cerebral hemispheres can result in **holoprosencephaly** (failure of forebrain development), which involves impaired cleavage of the cerebral hemispheres and associated facial malformations. Although this malformation is most commonly genetic in origin, similar disturbances in brain development can be seen after alcohol exposure (fetal alcohol syndrome) or retinoic acid exposure (high-dose vitamin A given for treatment of severe acne) during early embryonic development (Edison & Muenke, 2003).

High blood sugar levels, seen in mothers with uncontrolled diabetes, can act as a teratogen during embryogenesis, resulting in **caudal agenesis**—a condition in which there is **hypoplasia** (underdevelopment) and fusion of the lower limbs along with pelvic and **sacral** (base of the spine) anomalies (Sadler, 2015).

The emergence of **laterality** (dominance of right or left side) is also vulnerable to injury and maldevelopment during embryogenesis. The heart is the primary organ with significant laterality (left side dominant), and disruptions in the emergence of laterality leave the fetus particularly vulnerable to the development of critical congenital heart disease (e.g., hypoplastic left heart syndrome).

This period in development further coincides with neurulation, so that individuals with abnormal arrangements of body organs are also prone to “midline defects,” including neural tube defects, cleft palate, and **omphaloceles** (a midline abdominal wall defect).

Fetal Period

Major structural malformations are less likely to occur in the fetal period, as most body organs have already formed. Rather, this period is marked by a vulnerability to disruptions in the typical growth and development of existing body organs. Environmental influences and toxins become increasingly important, as does the dose, duration, and developmental stage at the time of exposure (see Chapter 2). The fetal period marks the time for proliferation, organization, and refinement of the neuronal circuitry of the brain that, if altered, can lead to the emergence of developmental disabilities. The next section of this chapter emphasizes the most common mechanisms of fetal injury, particularly brain injury, during the fetal period. These mechanisms include the following: 1) infection; 2) inflammation; 3) hypoxia, hypoperfusion, and ischemia; 4) polysubstance use and abuse; and 5) maternal stress, anxiety, and depression.

Infection The developing fetus is susceptible to injury from infections for a number of reasons. First, as previously discussed, alterations in the mother’s immune system leave her vulnerable to infections. Maternal infections can spread to the fetus through multiple routes: transplacental, ascending, and perinatal transmission. **Transplacental transmission** refers to the passage of microbes from the maternal to fetal circulation via the placenta. **Ascending infections** refer to the transfer of microbes from the maternal genital tract through the cervix and across the amniotic

membranes to the fetus. **Perinatal transmission** refers to the transfer of infection during the passage of the infant through the cervix during delivery.

Congenital infections affecting the fetus and newborn can occur at any time during pregnancy. The GA at exposure reflects different periods of fetal vulnerability and explains the wide spectrum of clinical symptoms that may be present at birth. Early exposures to infectious agents in pregnancy, particularly to certain viruses, can result in interruptions of cellular division and proliferation in addition to the direct viral effect of **cytotoxicity** (cellular toxicity) and cell death. As a result, it is not surprising that early exposure to many types of viruses can result in microcephaly and overall fetal growth restriction. The mother’s immune status and pre-pregnancy exposures also impact the effect of viral infections on fetal development.

CMV is one of the most common congenital infections and can result in premature birth, growth restriction, microcephaly, seizures, and hearing loss. Up to 60% of women will have been exposed to CMV prior to pregnancy, so only 40% are susceptible to primary infection during pregnancy (Staras et al., 2006). There may be few or no symptoms of CMV infection in the mother. If symptoms do occur, they tend to be mild and include muscle aches, fatigue, and low-grade fever. For women who are susceptible to CMV infection, fortunately less than 10% will acquire the infection during pregnancy and expose their fetus to the virus (Hyde, Schmid, & Cannon, 2010).

Many infants with congenital CMV are asymptomatic at birth but present with neurodevelopmental delays later in life. Up to 15% of affected infants will manifest hearing loss, visual impairment, and intellectual disability within the first few years of life but without microcephaly (Fowler & Boppana, 2018). This group likely reflects later exposure during fetal life. As a result, early neuronal proliferation is preserved, resulting in a typical head size; however, disruption of neuronal migration and organization can lead to cognitive impairment (Silasi et al., 2015).

This contrasts with congenital herpes simplex virus (HSV), in that the vast majority of newborns contract HSV infection during delivery. For women with existing antibodies (up to 70% of the population), the risk of HSV transmission to the fetus is fortunately quite low. There is, however, nearly a 50% risk of transmission if the mother acquires her first HSV infection during pregnancy. For newborns who acquire perinatal HSV and develop **encephalitis** (brain infection) after birth, more than two thirds of survivors will manifest neurodevelopmental abnormalities even if they have received adequate

antiviral therapy (James, Kimberlin, & Whitley, 2009; Shankar, Patil, & Skariyachan, 2017; Silasi et al., 2015).

The immature fetal immune system also contributes to the impact of congenital infections. **Congenital varicella syndrome (VZV)** occurs when the embryo or fetus is exposed to the varicella virus in the first 20 weeks of pregnancy and can result in microcephaly, intellectual disability, limb hypoplasia, and/or growth restriction. Although lifelong immunity is common after exposure to varicella as a child or adult, it is believed that congenital VZV results from reactivation of the virus transmitted by the mother to the fetus in the absence of a functioning fetal immune system (Lamont et al., 2011; Smith & Arvin, 2009).

The outbreak of **Zika virus** in Central and South America in 2015 identified this virus as a previously unrecognized teratogenic agent. Neuronal stem cells are particularly sensitive to the Zika virus, resulting in exaggerated cell death in the frontal and parietal lobes of the fetal brain. This can lead to microcephaly and intellectual disability that is more severe than in other congenital infections.

Although risks of fetal viral infection persist, advances in medicine have positively influenced the **vertical transmission** (passage from mother to infant during the period immediately before and after birth) of certain microbes. The prime examples are Rubella and human immunodeficiency virus (HIV). Rubella virus in pregnancy is associated with the development of cataracts, glaucoma, heart defects, intellectual disability, hearing loss, and dental anomalies in the progeny. However, the rates of congenital rubella have decreased dramatically since the 1970s as a result of the routine administration of the rubella vaccine to children, providing lifelong immunity (Silasi et al., 2015).

Advanced therapies for the treatment of HIV can reduce maternal viral counts to virtually undetectable levels and markedly decrease the risk of transmission of the virus from mother to child. However, elucidating the fetal impact of congenital HIV has been challenging, as the effects of the virus versus those of antiretroviral treatment are difficult to distinguish. The overall prevalence of birth defects in this population is estimated to be approximately 5%–7%, primarily affecting musculoskeletal and cardiovascular development (Williams et al., 2015).

Complicating the assessment of the impact of early infectious exposures on the developing fetus is evidence that **hyperthermia** (fever) associated with any infection can be teratogenic. Particularly in the embryonic period, elevated maternal temperature is associated with an increased risk of major malformations. Other viruses such as parvovirus B19 may not be

teratogenic but can nonetheless cause significant fetal harm. Parvovirus has a predilection for destroying red blood cells, leading to fetal anemia, hypoxemia, and high-output cardiac failure. While not directly targeting the brain, cardiovascular collapse in the fetus can affect both survival and neurodevelopment (Ornoy & Ergaz, 2017; Sass et al., 2017).

Inflammation Acute and chronic inflammation, even in the absence of intrauterine infection, is associated with poor pregnancy outcome, including preterm birth, neonatal encephalopathy, and perinatal mortality. Chronic inflammation (most commonly **chorioamnionitis**) alone increases the chance of preterm delivery and potentially related brain injury. The severity of fetal inflammation at delivery has been associated with an increased risk of neurodevelopment disabilities, most prominently cerebral palsy. Placental inflammation has also been associated with fetal growth restriction, an independent risk factor for neurodevelopmental disabilities (Greer et al., 2012; Salas et al., 2013).

Hypoxia, Hypoperfusion, and Ischemia In critical congenital heart disease (CCHD), the normal patterns of blood circulation are disrupted, resulting in chronic **hypoxia** (lower than normal levels of circulating oxygen). Numerous neurodevelopmental abnormalities have been described in this population. Impaired brain growth and maturation is most impacted by hypoxia and hypoperfusion in the third trimester when there is a particularly high demand for nutrients because of rapid body growth (Clouchoux et al., 2013).

Chronic hypoxia is also seen when there is placental insufficiency. The result is fetal growth restriction and low birth weight. As with CCHD, many survivors of fetal growth restriction are at risk for lifelong motor, cognitive, and behavioral impairments (Malhotra et al., 2017).

As is true with chronic hypoxia, low perfusion states of the fetus can also result in neuro-developmental impairment (Ghi et al., 2004). In addition to parvovirus infection, conditions associated with fetal anemia (e.g., **Rh incompatibility**, in which maternal antibodies cross into the fetal circulation and destroy fetal red cells) can result in hypoperfusion and hypoxia.

Polysubstance Use and Abuse The maternal use of alcohol, cigarettes, marijuana, illicit drugs, and opioids during pregnancy can have a significant adverse impact on fetal health. Some of these substances have direct teratogenic effects on the fetus (see

Chapter 2), whereas others influence brain biochemistry through alterations in neurotransmitters. Some have direct toxic effects on the placenta, but all impact maternal behavior and health.

Alcohol exposure during pregnancy can result in a spectrum of disorders. The most severe form is fetal alcohol syndrome, a condition with profound physical, cognitive, and behavioral disabilities that likely results from early and high exposure to alcohol in the embryonic period. Alcohol also is toxic to the placenta, exacerbating placental disease and disrupting the normal hormonal functions of the fetal-placental unit.

Nicotine and smoking exposure throughout pregnancy is associated with fetal growth restriction and low birth weight as a result of decreased utero-placental and fetal umbilical vessel blood flow (Behnke, Smith, Committee on Substance Abuse, & Committee on Fetus and Newborn, 2013; Thakur et al., 2013). Nicotine also activates numerous brain pathways, including cholinergic, GABA, and glutamate receptors. These pathways are also activated by other compounds from cigarettes and smoke, including cyanide and cadmium. It is likely that these altered pathways play a role in the increased incidence of subsequent neurobehavioral and cognitive impairments (e.g., ADHD) in the child (Lin et al., 2017).

Cocaine and other stimulants increase dopamine and serotonin pathways, and opioids mimic natural endorphins and also activate those pathways. The increase in both legal (prescription opioid-containing pain medication) and illicit (heroin) opioid use during pregnancy in the United States has been so dramatic in recent years that it has reached epidemic proportions (Brown, Doshi, Pauly, & Talbert, 2016). Although the prescribed use of methadone and buprenorphine has helped individuals with heroin dependency and decreased the symptoms of neonatal abstinence syndrome, the long-term effects of these medications on fetal neurodevelopment is not well known (Jansson et al., 2017).

Maternal Stress, Anxiety, and Depression

Maternal stress has been known to influence the immune system of both mother and fetus and has been associated with deviations in neurodevelopment and neuropsychiatric conditions. Maternal stress hormones also are known to cross the placenta, stimulating the fetal stress axis and releasing fetal cortisol. Early fetal exposure to these stress hormones is associated with preterm delivery, long-term metabolic effects on the child (including obesity and hypertension), and altered behavioral and cognitive function.

Structurally, prenatal stress levels have been correlated with volumetric changes in the hippocampus

and amygdala of the brain and in subsequent behavior in affected children, suggesting that early fetal exposures influence brain growth and development (Marques, Bjorke-Monsen, Teixeira, & Silverman, 2015). Advanced imaging of the brain that can identify and describe neuronal microstructure suggests that neural pathways in newborns exposed to maternal anxiety differ from healthy controls, particularly in regions of the brain controlling sensory and emotional processing (Rifkin-Graboi et al., 2015).

Maternal depression and depressive symptoms are common during pregnancy and the postpartum period. Maternal depression has been found to be associated with preterm delivery, decreased placental function, growth restriction, and increased neonatal complications. It also has been associated with subsequent developmental delays and behavior problems (increased anxiety and attention problems) in children born to these mothers.

Many women receive psychopharmacologic therapy during pregnancy. Selective serotonin reuptake inhibitors (SSRIs) are the most common medications prescribed for depression in pregnancy. Studies suggest SSRIs may increase the rates of miscarriage and preeclampsia, preterm birth, and fetal growth restriction (Andersen, Andersen, Horwitz, Poulsen, & Jimenez-Solem, 2014; Eke, Saccone, & Berghella, 2016), although it is unclear if these rates are higher in mothers with untreated depression compared with those with SSRI exposure. There are mixed reports of early SSRI exposure and congenital anomalies, although this risk seems small. Some studies suggest that prenatal SSRI exposure may impact neurodevelopmental outcome, although long-term studies on this relationship are lacking. Animal studies suggest that the type of antidepressants, the timing, and cumulative exposure can each influence fetal neurodevelopment (Olivier et al., 2013).

EVALUATION OF FETAL DEVELOPMENT

The primary tool for the evaluation of fetal development is a detailed medical history that elicits genetic and environmental risk factors (including dietary and lifestyle habits), as well as potential toxic and viral exposures. Routine screening for fetal maldevelopment involves obtaining maternal blood samples that measure pregnancy-specific biomarkers. Recent advances in genetic testing can now extract fetal DNA (cell-free DNA) from the maternal circulation (see Chapter 3). This process permits the prenatal diagnosis of chromosomal anomalies without the need for invasive procedures that carry risk to the developing fetus (i.e., amniocentesis and chorionic villus sampling). Fetal

imaging, through ultrasound or magnetic resonance imaging, can also give significant insight into the developing fetus.

DIAGNOSTIC CONSIDERATIONS

Although the availability of cell-free DNA technology has transformed prenatal testing, there remain significant limitations. This technology has been best studied in the identification of chromosomal anomalies; the detection of nonchromosomal conditions is less reliable and currently not commercially available. For definitive genetic testing, the gold standard remains the evaluation of fetal tissue, either through chorionic villous sampling of the placenta or amniocentesis.

Similarly, advances in prenatal imaging have revolutionized the identification of major structural anomalies. However, structure and function are not synonymous, and clinicians are limited in predicting functional outcome from structural alterations alone. These limitations are most pronounced in the prognostication of neuropsychiatric and neurobehavioral conditions in which fairly normal structural evaluations of the brain are generally obtained.

OVERVIEW OF MANAGEMENT STRATEGIES

A significant challenge in the medical evaluation and care of the developing embryo/fetus is that severe malformations often occur before the mother is even aware she is pregnant. Therefore, many strategies to optimize pregnancy outcomes emphasize the initiation of care in the preconception period. Pre-pregnancy vaccinations and micronutrient supplementation are two interventions that have dramatically improved pregnancy outcomes.

Advances in obstetric and perinatal care now allow for direct intervention of the fetus *in utero*—particularly for the early correction of major malformations. As one example, fetal surgery for the repair of neural tube defects may improve outcomes by preventing secondary injury to the developing spinal cord. Another example is fetal cardiac interventions, which may improve fetal circulation and ameliorate future neurodevelopmental impairment.

Other interventions are being developed to optimize utero-placental health through novel medications and nutritional supplements. Successful mammalian models of an artificial placenta present the possibility of having the human fetus grow outside of the uterus when the intrauterine environment will no longer sustain it (Partridge et al., 2017). These promising new

therapies have the potential to transform fetal care, particularly in the setting of an adverse intrauterine environment, and revolutionize the way clinicians consider neuroprotection to prevent fetal derived developmental disabilities.

SUMMARY

- Fetal health involves a complex interplay of fetal-maternal-placental well-being. Specific adaptations of the fetal and placental circulations optimize nutrient transfer to the fetus, especially the fetal brain.
- Human development follows a highly structured pattern of development from conception through fetal development. The rapidly developing fetal brain results in varying periods of vulnerability throughout gestation, during which even the subtlest alteration can give rise to lifelong consequences.
- The placenta is a critical organ of fetal development that performs important nutritional, immunologic, and endocrine functions to support the developing fetus.
- Deviations from normal development can result from maternal, fetal, or placental disturbances. Such deviations may be genetic in origin or secondary to acquired illness, injury, or toxic exposure.
- A detailed medical history can identify a significant number of risk factors for developmental disorders in the fetus. Maternal serum testing and fetal testing through amniocentesis or chorionic villous sampling, along with structural evaluations of the fetus through ultrasound and magnetic resonance imaging, can aid in the diagnosis of many fetal conditions.
- Accurate fetal diagnostics will become increasingly important as novel fetal interventions become available.

CHAPTER 7

The Senses

The World We See, Hear, and Feel

Louis Pellegrino

Upon completion of this chapter, the reader will

- Explain the ways in which individuals use their senses to adapt to the world around and within them
- Describe the anatomy of vision and the development of the visual system
- Identify common methods of screening for vision problems
- Describe the anatomy of hearing and the development of the auditory system
- Identify common methods of screening for hearing problems
- Describe the components of the somatosensory system and their relationships to motor control and coordination

We often take for granted the great gift that we have in our senses. At every moment, our brains are awash with signals transmitted from myriad sensory receptors throughout our bodies, allowing us to sense the world around us and the world within us. The brain is, in fact, the primary sensory organ, and our eyes, ears, and other sensory organs serve to translate information in the environment and in our bodies into nerve impulses that the brain can use and understand.

The traditional “five senses” (vision, hearing, touch, smell, and taste) represent an oversimplification of the true complexity of the human sensory apparatus (Table 7.1). This chapter focuses on those systems of special relevance to developmental disabilities: the visual, auditory, and somatosensory systems. Emphasis is placed on the anatomy and development of these systems and on screening procedures used to identify vision, hearing, and sensory integration problems.

Impairments of vision are discussed in detail in Chapter 25, impairments of hearing are discussed in Chapter 26, and sensory processing impairments as they relate to autism spectrum disorder are discussed in Chapter 18.

THE WORLD WE SEE

Humans are creatures of vision. More than any of the other senses, individuals rely on vision to keep track of the world around them. Even language is dominated by vision-related metaphors (e.g., “I *see* what you mean,” “A good leader must have a *clear vision* for the future,” “We need to *take a look at* that issue more closely,” and “You don’t have *the big picture*”). At some point in our lives, most individuals will experience challenges with vision that require professional attention, especially as they age. Yet, vision problems are also common in

Table 7.1. The human sensory apparatus

The chemical senses (sensing chemical substances through direct contact with sensory organs)		
Name	Primary receptor(s)	Neurologic destination
Taste	Taste receptors for salt, sweet, bitter, sour, and umami (savory) located in the taste buds of the tongue, palate, and pharynx	Gustatory cortex (part of the parietal cortex) via nuclei in the brainstem and thalamus
Smell (olfaction)	Olfactory cells located on the inner surfaces of the nasal cavity	Direct pathway from receptor cells to the primitive olfactory cortex; indirect pathways via the thalamus to the orbital frontal cortex
The remote senses (sensing energy sources from the external environment)		
Vision	Photoreceptors in the retina (rods and cones) transduce electromagnetic energy into nerve impulses	The visual cortex via the brainstem and thalamus
Hearing	Transduction of acoustic energy (pressure/sound waves) by hair cells in the cochlea into nerve impulses	The auditory cortex via the brainstem and thalamus
The internal senses (sensing changes inside the body and on body surfaces)		
Balance	The vestibular apparatus (of the inner ear) senses the position and movement of the head via movement of fluid within the semicircular canals, which is transduced by hair cells into nerve impulses	Output from the vestibular apparatus to multiple centers in the brain and spinal cord help regulate movement
Touch, pressure, pain, temperature	Mechanoreceptors (touch and pressure), nociceptors (pain), and thermoreceptors (temperature) in the skin	The somatosensory cortex via multiple pathways in the spinal cord, brainstem, and thalamus
"Body sense" (proprioception)	Stretch receptors (muscle spindles) and Golgi tendon organs sense active stretching and the state of tension in muscles and tendons; multiple receptor types sense movement and position of joints	Multiple pathways in the spinal cord and brainstem regulate motor output and movement, mostly at an unconscious level

children, especially those with developmental disabilities, and can have a significant impact on their lives.

The case study below illustrates the common issue of unidentified vision problems in children—especially younger children. In the United States, the prevalence of vision impairment in preschoolers aged 36 to 72 months is estimated to be 1.5%, which is equivalent to more than 174,000 children (Varma, Tarczy-Hornoch, & Jiang, 2017). Hispanic and African American children are at higher risk, and children with other developmental disabilities, such as cerebral palsy or intellectual disability, are at highest risk for visual problems. In fact, 75% of children with vision impairment have another developmental disability (Boyle et al., 2011).

■ ■ ■ CASE STUDY

Kayla is a smart, vivacious 7-year-old second grader who has been falling behind academically. She mastered her letters and numbers early in preschool and was reading first-grade material by the end of kindergarten. Her first-grade teacher described her as being one of her best students and a delight to have in the class. Her second-grade teacher saw a very different picture. Kayla seemed uncharacteristically distracted and didn't participate in classroom activities. She still enjoyed reading on her own,

loved playing with her friends during recess, and seemed to learn well when her teacher worked with her one-on-one, but during group instruction she missed much of what was being taught. She wasn't being bullied and wasn't having problems at home.

Kayla's mother and teacher were both at a loss to explain the change in her demeanor. Early in the school year the school nurse performed vision screening on all of the students, and Kayla's mother and teacher were both surprised to learn that Kayla failed the screen. She was seen by an optometrist, who discovered that Kayla was near-sighted, or myopic, and had difficulty seeing distant objects. Once Kayla was fitted with glasses, she quickly recovered her enthusiasm for learning. Her teacher was amazed by the transformation and felt that she working with a different child. Her mother felt like she had her old Kayla back.

Thought Questions:

What measures could be taken to improve the identification of young children with vision problems? If a child has passed his or her newborn hearing screening test, is further testing ever necessary? If so, under what circumstances? How might an awareness of sensory processing problems in children influence the design of schools and classrooms?

Anatomy of the Visual System

The eye is the primary organ of vision (Figure 7.1). It is designed to transduce a portion of electromagnetic radiation, visible light, into nerve impulses that can be processed by the brain. Light first enters the eye through the **cornea**, a transparent tissue that is the primary refractive surface of the eye (Figure 7.2). The curved surface of the cornea bends (refracts) light so that it converges on the retina, the light-sensitive surface lining the back of the eye.

The amount of light that enters the eye is regulated by the contraction and relaxation of the donut-shaped **iris** (the colored part of the eye), which controls the size of the central **pupil**. The **lens** further focuses light through the central cavity of the eye (which is filled with a gelatinous fluid, the **vitreous humor**) onto the **retina**. The retina contains two types of photoreceptive cells, the **cones**, which respond to differences in color (related to the frequency of light waves), and the **rods**, which are sensitive to differences in brightness (related to the amplitude of light waves). There are three types of cones: 1) those that are most sensitive to low-frequency (red) light, 2) those most sensitive to mid-frequency (green) light, and 3) those most sensitive to high-frequency (blue) light. The cones are concentrated in the central area of the retina (the **fovea**) and subserve color vision for detail in bright daylight.

Figure 7.1. The anatomy of the eye. The eye is often likened to a camera. The pupil is like the shutter of a camera, which opens and closes to admit more or less light. Light is transmitted through the transparent tissues and fluids of the eye (the cornea, the fluid of the anterior chamber, the lens, and the vitreous humor) to the retina, where light energy is transduced into nerve impulses, which are then transmitted to the brain via the optic nerve.

Figure 7.2. Refraction of light by the cornea and lens. The cornea, which is situated between the surrounding air and the fluid interior of the eye, is the primary refractive surface of the eye. Muscles attached to the lens change its shape, refining the focus of images falling on the fovea, the most sensitive center of vision on the retina.

Each cone is connected through intermediary cells to a single ganglion cell in the retina. Ganglion cells are the first in a series of nerve cells (neurons) that transmit information from the retina to the brain. This one-to-one arrangement of cones to ganglion cells ensures a high degree of accuracy in encoding detailed spatial information about the visual environment. Rods are far more numerous than cones, and they populate the periphery of the retina. They are most sensitive in low light conditions, and many rods tend to connect to individual ganglion cells, in effect amplifying their sensitivity in low light conditions. Because rods are not specifically responsive to particular colors, low light vision lends a grayish or dark blueish-green cast to the visual environment (Bear, Connors, & Paradiso, 2016).

Spatial information about the visual environment is “mapped” onto the retina, and that information is transmitted more or less intact throughout the nervous system. Fibers from the ganglion cells bundle together to form the right and left optic nerves, which meet at a crossroad in the visual system called the optic chiasm. At this point, nerve fibers carrying information about the left visual field *from both eyes* continue toward nerve centers on the right side of the brain, and fibers carrying information about the right visual field *from both eyes* continue toward nerve centers on the left side of the brain. In effect, the right brain sees the left side of the world, and the left brain sees the right side of the world.

Next, nerve fibers arrive at the “Grand Central Station” of vision in the brain, the lateral geniculate body of the thalamus. The thalamus is the major waystation in the brain for all types of sensory information, and visual information here “changes trains” and is

transmitted to its final destination, the primary visual cortex.

The visual cortex, located in the back of the brain in the occipital lobe, has remarkable computational powers. Different modules within the cortex analyze different aspects of the visual environment, such as the shape and configuration of objects, color, and motion. Visual information is then processed further along two pathways in the cortex, the dorsal pathway and the ventral pathway (Figure 7.3). The dorsal pathway, sometimes referred to as the “where” or “action” stream, analyzes spatial information in the environment and is thought to aid the motor control system in planning movement. The ventral pathway, sometimes referred to as the “what” or “perception” stream, provides for object recognition and is thought to aid various higher-level cognitive processes involved in perception and memory (Goodale & Milner, 1992). A special area in the ventral pathway is dedicated to facial recognition, and damage to that area can result in a condition sometimes called “face blindness.” Affected individuals have normal vision and object perception but cannot recognize people’s faces, including close family members.

Development of Vision

In the human embryo, the eyes develop as a direct outgrowth of the embryonic brain (Figure 7.4). The first rudimentary precursors to the eyes appear at 4 weeks’ gestation. By 7 weeks, the eyes have assumed their basic form, and by 15 weeks, they are fully formed.

In contrast to the auditory system, which receives significant stimulation prenatally, the visual system

receives no input prior to birth. Infants are not born blind, however. Studies have demonstrated that they have at least a vague awareness of their visual environment, and quite early in infancy they demonstrate a preference for faces over other objects (Bremond-Gignac et al., 2011). Newborns have fewer cones in the retina than adults and so have limited color perception. They also have a lower density of connections in the thalamus and visual cortex compared with adults. Control of eye movements is also immature. Newborns can briefly fix their gaze on objects or faces, but their eyes often don’t move together (this is called dysconjugate eye movements or gaze).

By 3 months of age, infants are able to fix on and follow objects with their eyes and the eyes consistently move together (conjugate gaze). By this age, infants also will blink in response to a visual threat (e.g., an object moving toward the face quickly), and they will attempt to coordinate vision with movement (e.g., reaching toward and batting at objects).

By 5 to 8 months of age, infants demonstrate evidence of improved color vision and depth perception, and from a neurologic perspective, they have achieved the highest synaptic density of connections within the visual system that they will ever have during their lifespan. These connections are gradually “pruned” as the visual system matures in a similar way to what happens in the brain. This high level of connectivity relates to the great plasticity of the visual system in infancy and early childhood. The immature nervous system in general, and the visual nervous system in particular, is better able to respond and adapt to visual and visual motor disturbances. For this reason,

Figure 7.3. The ventral and dorsal visual pathways of the cortex. Visual data received by the primary visual cortex are further analyzed to provide visual context for movement (the “where” stream, located along the upper, or dorsal, surface of the brain) and to provide information for analysis of the details of the visual environment (the “what” stream, located along the lower, or ventral, surface of the brain).

Figure 7.4. The embryonic development of the eye. The eyes first appear at 4 weeks' gestation as two spherical bulges, one on each side of the head. They indent in the next week to form the optic cups. By 7 weeks, the eyes have already assumed their basic form. The eye is completely formed by 15 weeks.

treatment of these problems earlier rather than later in childhood will result in more favorable outcomes for vision (see the discussion on amblyopia in Chapter 25). By 3 to 4 years of age, measures of visual acuity will generally average 20/40, and by 6 years of age, children achieve adult levels of visual acuity (fully mature vision), ideally 20/20.

Measuring Visual Acuity

When someone says, "I have 20/20 vision," it is understood that they have excellent vision and probably don't need glasses. The term 20/20 derives from how well an individual can see the lines on a standard eye chart. The first 20 in this ratio refers to the standard distance (20 feet) that a person would stand from the eye chart when being tested (for convenience, however, many charts are designed to be used at a distance of 10 feet). Vision is usually tested separately for each eye (the eye not being tested is covered). If the person being tested can see items on a chart that an adult with normal vision can see at 20 feet, that person is said to have 20/20 vision. If, on the other hand, the person being tested can only see items on the chart that adults with normal vision would be able to see at a distance of 40 feet, that person is said to have 20/40 vision. The larger the bottom number, the worse the vision. A person with

20/70 has a significant visual impairment and is said to have low vision; a person with 20/200 vision is said to be legally blind.

Different eye charts are used to test vision at different ages. The classic Snellen eye chart uses letters and should only be used in adults and older children who can read. Eye charts used for testing younger children include the HOTV chart, which uses various sizes of the capitalized letters *H*, *O*, *T*, and *V*. The child is asked to match the letter she sees to an example of the letters held close by the examiner (the child does not have to name the letters). Lea charts similarly use simple visual symbols (a circle, a square, and simplified drawings of a house and an apple) that a child is asked to match. Children as young as 2 to 3 years of age may be tested in this manner (American Academy of Ophthalmology, 2016; Rogers & Jordan, 2013).

Screening for Vision Problems

Whereas universal screening of newborns for hearing problems has become the norm (see discussion below), there is still a lack of consensus about how best to approach the issue of screening for visual deficits in young children. There is general agreement that vision problems should be identified as early as possible, that the process of surveillance for such problems should

begin at birth, and that primary care providers (such as pediatricians and family practice physicians) have a particular responsibility to identify the risk factors for and the early signs of visual impairment (see Box 7.1 for a discussion of the role of schools and the school nurse in screening for vision problems). There is also agreement that children should have their vision screened using standard eye charts as early as possible (ideally beginning at 3 years of age).

Children who fail vision screening, have significant risk factors for visual impairment, or demonstrate abnormalities on examination of their eyes, including dysconjugate gaze, should be referred to a vision specialist for a comprehensive evaluation. Table 7.2 provides a summary of current recommendations for evaluation and referral. Recommendations have been made for all children to have a comprehensive assessment as early as 6 months of age (American Association for Pediatric Ophthalmology and Strabismus, 2017), but there are concerns that this would represent an inefficient use of resources. Likewise, attempts to provide universal screening outside of primary care settings have met with mixed results (Kemper, Fant, & Badgett, 2003; Rogers & Jordan, 2013).

Screening very young children (especially those less than 3 years old) represents a particularly difficult problem, but technology has provided answers. Instruments referred to as photoscreeners and autorefractors are available that allow testing of children as young as 1 year of age. These methods are noninvasive (for photoscreeners, the process is as simple as taking the equivalent of a snapshot of the child's eyes), require minimal cooperation from the child, and can be used in children who cannot be reliably screened using eye charts.

Instrument-based screening may actually be superior to eye charts for 3- to 6-year-olds (O'Hara, 2016). Limitations for their use include the initial cost of the instruments and lack of insurance coverage for the procedure. Despite these difficulties, the American Academy of Pediatrics and the American Academy of Ophthalmology have endorsed their use in recently published guidelines (Miller & Lessin, 2012).

THE WORLD WE HEAR

If vision is a window on the world, hearing is a gateway into the thoughts and feelings of others. Compared with vision, hearing is a more intrusive sense; individuals cannot stop hearing as easily as they can stop seeing by closing their eyes. Humans are constantly bathed in a sea of sound, and a primary task of the auditory system is to filter out the noise and allow individuals to focus on those things that are most important to hear. Very often, the things that are most necessary to hear are the words spoken by others.

In the course of early development, human beings are unique in their ability to become attuned to the discrete units of sounds (phonemes) of their native language (Juszyk, 2002). Our capacity to speak and to understand others is critically dependent on this ability. Ensuring that children are born with intact hearing and thus have a clear path to learning to speak their native language is a high priority for parents and professionals alike.

The most common cause of temporary hearing loss in young children is otitis media with effusion (OME), an ear infection with middle ear fluid. By 1 year of age, 62% of children have had their first episode of

BOX 7.1 INTERDISCIPLINARY CARE

The School Nurse and Vision Screening

Because children typically have the most contact with their primary care providers (i.e., pediatricians, family practitioners, nurse practitioners, and physician assistants) through early childhood, these professionals have the greatest responsibility for identifying vision problems. Despite efforts to improve screening practices in these settings, shortfalls persist in this process (see text for discussion). The school nurse can serve as a crucial "safety net" in identifying children with vision problems who may have been previously missed. Vision problems may surface for the first time in elementary or middle school, and the school nurse is ideally situated to recognize these problems by providing in-school screening and by referring children for further assessment.

Guidelines exist for screening children through elementary school and beyond (Colorado Department of Education, 2017; National Association of School Nurses, 2017). School nurses are also well positioned, through their regular contact with students and teachers, to recognize children who may have "red flags" for vision problems (e.g., unexplained reading difficulties, unexplained deterioration in general academic performance).

Table 7.2. Vision screening recommendations

Age	Evaluation	Reasons for referral to vision specialist
Newborn–1 year	Examine eyes (external inspection) Assess vision (response to light younger than 3 months, fixation and following older than 3 months) Perform red reflex evaluation (looking for absent or asymmetric reflex) ^a Perform pupillary examination Review family history	Abnormal red reflex (urgent consultation) Family history of retinoblastoma in parent or sibling Refer any infant with poor tracking or eye misalignment in child younger than 3 months old
1–3 years	Obtain ocular history Examine eyes, lids, visual reactions, and eye alignment and motility with use of ophthalmoscope Perform pupillary examination Perform red reflex evaluation Use screening device (e.g., photostrengthening, autorefraction), if available Perform visual acuity testing (HOTV, LEA symbols) in some 2- to 3-year-olds	Abnormal eye movements (strabismus) Chronic tearing or eye discharge Failed visual acuity testing Failed photostrengthening
3–5 years	Obtain ocular history Examine eyes, lids, visual reactions, and eye alignment and motility Perform pupillary examinations Perform red reflex evaluation Perform visual acuity testing (HOTV, LEA symbols) Use a screening device, if available	Failed visual acuity test: 3–4 years: Cannot identify most items at 20/50 4–5 years: Cannot identify most items at 20/40 Two-line difference between eyes on visual acuity test Failed photostrengthening
5 years and older	Perform ocular history Examine eyes, lids, visual reactions, and eye alignment and motility Perform pupillary examinations Perform red reflex evaluation Perform visual acuity testing (every 1–2 years)	Failed visual acuity test: Cannot identify most items at 20/30 Two-line difference between eyes on visual acuity test Trouble reading
At-risk children (any age)	Perform ocular history Examine eyes, lids, visual reactions, and eye alignment and motility Perform pupillary examinations Perform red reflex evaluation Perform visual acuity testing	Retinopathy of prematurity Family history of retinoblastoma, congenital glaucoma, congenital cataracts Other medical conditions associated with eye and vision problems Nystagmus (involuntary “jiggling” eye movements) Developmental delay, disability

Sources: American Association for Pediatric Ophthalmology and Strabismus (2017), Donahue and Baker (2016), and Rogers and Jordan (2013).

^aRed reflex evaluation: Examine both eyes simultaneously from approximately 1 to 2 feet away, using an ophthalmoscope to view the red reflection (reflex) of the retina of each eye seen through a child’s pupils (identical to the red-eye effect seen when taking a photograph). The red reflex should have a typical red appearance and should be the same brightness in each eye. If the appearance is abnormal (e.g., white or cloudy instead of red) or if the red reflex for one eye differs from the other, the child should be referred for a comprehensive vision assessment.

otitis media, and by 3 years of age, 83% of children have been affected (Rosa-Olivares, Porro, Rodriguez-Varela, Riefkohl, & Niroomand-Rad, 2015). Otitis media may develop during an upper respiratory infection, spontaneously as a result of eustachian tube dysfunction, or as a delayed sequelae of acute otitis media. Regardless of the etiology, if the middle ear infection is associated with effusion, it may cause a temporary conductive hearing loss that can impact language development if prolonged. Because OME is painless, it may escape diagnosis, but it should be carefully assessed for in children with delayed language development.

Current guidelines recommend tympanostomy tube placement for OME of 3 months or more duration

(termed chronic) if it causes hearing loss (Rosenfeld et al., 2013). Tympanostomy tubes are surgically inserted, serve to aerate the middle ear, and help prevent future episodes of acute otitis media and OME. They typically extrude spontaneously within 1–2 years after insertion. Placement of tympanostomy tubes is the most common outpatient surgery performed in the United States. In fact, nearly 1 in 15 children will have tympanostomy tubes placed by 3 years of age (Rosenfeld et al., 2013).

Although the hearing loss associated with OME is most often a mild to moderate conductive hearing loss, moderate to profound persistent hearing loss from all causes occurs in about 4.5 out of every 1,000 children (Boyle et al., 2011). Significant hearing problems

are especially common among children with other developmental disabilities, particularly trisomy 21 (discussed in detail in Chapter 26).

■ ■ ■ CASE STUDY

Henry is a 2-and-a-half-year-old boy with delayed speech and articulation errors. He passed his newborn hearing screen, but beginning in infancy he developed recurrent episodes of otitis media in one or both ears, as diagnosed by his pediatrician, Dr. Mendez. The acute inflammation always resolved with antibiotic treatment; however, Dr. Mendez has noted persistent fluid in the middle ear on several occasions. Henry has had three separate episodes of acute otitis media in the past year and persistent OME for the past 4 months. Henry's parents are concerned that these otologic problems may be affecting his speech and ask Dr. Mendez to test his hearing. She tells them that it would be best to have Henry tested by an audiologist. She also makes a referral to an otolaryngologist for consideration of placement of tympanostomy tubes. In the meantime, Henry has been evaluated by his county early intervention team, and he is receiving home-based speech therapy.

Anatomy of the Auditory System

The ear is designed to convert the mechanical energy of sound waves into nerve impulses that can be processed by the brain (Figure 7.5). The external ear and middle ear serve to transmit and amplify sound; the inner ear converts sound waves into nerve impulses, which are transmitted via central auditory pathways to the auditory cortex.

Figure 7.5. The anatomy of the ear. The external ear includes the auricle and the ear canal. The middle ear is composed of the tympanic membrane, or eardrum, and the three ear bones—the malleus, the incus, and the stapes. When the eustachian tube, which aerates the middle ear, is not functional, otitis media may develop. The stapes footplate lies on the oval window, the gateway to the inner ear. The inner ear contains the cochlea and the vestibular (balance) apparatus, collectively called the labyrinth.

The External and Middle Ear Sound waves are “collected,” in a sense, by the external ear. The external ear is composed of the pinna or **auricle** (the part of the ear that can be seen when looking in the mirror) and the ear canal, which has glands in its wall that produce ear wax, or cerumen. The auricle is designed to funnel sound through the ear canal toward the ear drum, or **tympanic membrane (TM)**, which lies at the end of the ear canal. The TM is made of thin, almost transparent tissue, and it vibrates readily in response to sound. It is attached to the **malleus** (Latin for “hammer”), which is the first in a series of tiny bones (called **ossicles**) that span the **middle ear** space. The malleus is rigidly connected to the **incus** (Latin for “anvil”), and the incus is flexibly connected to the **stapes** (Latin for “stirrup”). The flat face (footplate) of the stapes makes contact with a membrane covering the **oval window**, which is a part of the cochlea. This arrangement of TM-to-ossicles-to-oval window is designed to amplify the sounds that enter the ear. This is accomplished in two ways. The arrangement of the ossicles is such that they function as a lever, converting large but weak vibrations at the tympanic membrane into smaller but stronger vibrations at the oval window. The oval window also has a much smaller surface area than does the TM, which further serves to amplify the vibrations. Taken together, these two mechanisms amplify the sound pressure that reaches the oval window by a factor of 20 (Bear et al., 2016).

The Inner Ear The **cochlea** (Latin for “snail”) and the **vestibular apparatus** (the organ of balance) constitute the **inner ear**. The cochlea is designed to convert the mechanical energy of the amplified vibrations presented at the oval window into nerve impulses that can be transmitted to the brain. If the spiral-shaped cochlea were unraveled and straightened, it would look like three fluid-filled tubes running parallel to each other (Figure 7.6). One tube, called the **scala vestibuli (SV)**, originates at the oval window, and at its end encounters an opening (the helicotrema) that forms the origin of the **scala tympani (ST)**. The ST runs back along the length of the cochlea to end at the round window. The SV and ST are filled with a sodium-rich fluid called perilymph. Because the SV and the ST are continuous with each other, vibrations at the oval window are transmitted through the perilymph to the round window. In between the SV and the ST lies the **scala media (SM)**. In contrast to the SV and ST, the SM is filled with a potassium-rich fluid called endolymph.

The actual organ of hearing, the **organ of Corti**, runs along the base of the SM and rests on the **basilar**

Figure 7.6. The anatomy of the cochlea. In this illustration, the cochlea has been “unfolded” for simplicity. Sound vibrations from the stapes are transmitted as waves in the perilymph, leading to displacement of the organ of Corti (see Figure 7.7). High-frequency sounds stimulate hair cells close to the oval window, whereas low-frequency sounds stimulate hair cells further along the cochlea.

membrane (Figure 7.7). The organ of Corti is covered by the **tectorial membrane**. Between the basilar and tectorial membranes are a single row of inner hair cells and three parallel rows of outer hair cells. The

hair cells are anchored to the basilar membrane and have minuscule hair-like projections, called **stereocilia**, which project into the tectorial membrane. When pressure waves pass through the SV and ST, the basilar membrane is deformed and displaced, along with the attached hair cells, toward the tectorial membrane, causing the stereocilia to bend. When bent, tiny channels at the tips of the stereocilia open to allow an influx of potassium ions. This stimulates the release of an excitatory neurotransmitter, glutamate, which initiates nerve impulses in tiny tendrils projecting from the spiral ganglia of the auditory nerve. These impulses are then carried to the brain.

In summary,

1. Sound waves are funneled toward the tympanic membrane by the external ear.
2. The vibrations of the tympanic membrane are then transmitted and amplified by the ossicles, which create pressure waves in the fluid of the cochlea via the oval window.
3. These pressure waves displace the basilar membrane and with it the hair cells, causing a bending of the stereocilia that triggers (via the influx of potassium) the release of an excitatory neurotransmitter.
4. The release of glutamate initiates nerve impulses in the ganglion cells of the auditory nerve and completes the process of transduction of sound waves into nerve impulses.

Figure 7.7. The cochlea and the organ of Corti. The organ of Corti, the true organ of hearing, is located on the basilar membrane in the scala media of the cochlea. The inner and outer hair cells attach to the basilar membrane, and their stereocilia reach the overlying tectorial membrane. Sound waves cause movement of the basilar membrane relative to the tectorial membrane, stimulating the inner hair cells, which in turn synapse with ganglion cells of the auditory nerve, sending signals to the brain. The same movement stimulates the outer hairs to amplify the effect of sound on the cochlea.

Processing Sound Important details in this process relate to the nature of sound waves and the structural details of the middle and inner ears. Sound is, at its essence, a series of compression (pressure) waves transmitted through a medium, such as air. These pressure waves are usually depicted as sinusoidal waves, with peaks representing zones of compression and valleys representing zones of rarefaction (Figure 7.8). The waves are characterized by frequency (how close the waves are to each other, which relates to how many waves pass a given point in a given time interval) and intensity (the height of the waves). Frequency, which corresponds to **pitch** (whether a sound is high or low), is measured in Hertz (Hz, cycles per second), and intensity, which corresponds to loudness, is measured in decibels (dBs). Table 7.3 provides examples of decibel levels for representative environmental sounds.

The auditory system has a remarkable ability to modulate its response to both the intensity and frequency characteristics of sound. As sound waves are transmitted from the tympanic membrane to the ossicles of the middle ear, tiny muscles attached to the malleus and stapes contract or relax in response to the intensity (loudness) of the sound. Loud sounds cause contraction of the tensor tympani and the stapedius muscles to effectively reduce sound transmission through the malleus and stapes and protect the cochlea against sound injury.

When sound waves are transmitted into the cochlea via the oval window, the frequency (pitch) of the sounds is registered as a result of the special structural characteristics of the basilar membrane and the frequency-response characteristics of the hair cells. This membrane is narrower and stiffer at its origin near the oval window (the base) and wider and floppier at its terminus near the confluence of the scala vestibule and scala tympani. Because of this anatomy, more energetic, higher-frequency sounds are propagated shorter distances along the basilar membrane, and less energetic, lower-frequency sounds are propagated further along the basilar membrane. As a consequence, hair cells located near the base of the basilar membrane are situated to

Table 7.3. Volume of environmental sounds

dBA ^a	Example
0	Hearing threshold
10	Dropped pin
20	Rustling leaves
30	Whisper
40	Babbling brook
50	Refrigerator
60	Conversational speech
70	Shower
75	Vacuum cleaner
80	Alarm clock
85	Threshold for hearing loss due to cumulative exposure
90	Lawn mower
100	Motorcycle
110	Rock band
120	Thunderclap
130	Peak stadium crowd noise
140	Jet engine takeoff
150	Fighter jet launch

register higher-frequency sounds, and hair cells located near the apex of the basilar membrane are situated to register lower-frequency sounds. Because of this **tonotopic organization** of the cochlea, high-frequency and low-frequency sounds can be distinguished, and these distinctions can then be transmitted to the brain.

The phenomenon of **cochlear amplification** is another important factor in the process of sound transduction. As described above, sound waves are

Figure 7.8. Frequency and intensity of sound waves. The frequency of a sound, or its pitch, is expressed as cycles per second, or hertz (Hz). Middle C is 261.6 Hz; one octave higher (high C) is 523.3 Hz. Intensity of sound is expressed as decibels (dB) and varies from a whisper at 30 dB to a rock concert at 100 dB or more.

mechanically amplified in the middle ear as they are transmitted from the tympanic membrane to the oval window. In the cochlea, the movement of the basilar membrane in response to sound is further amplified by the action of the outer hair cells. When the outer hair cells are stimulated by specific sound frequencies, they contract and relax in response to the bending of the stereocilia, enhancing the movement of the basilar membrane to which they are anchored. The response time for this is nearly instantaneous and is mediated by a special motor protein in the cell membranes of the outer hair cells called prestin, from the Italian word *presto*, for fast (Bear et al., 2016).

A curious side effect of cochlear amplification is a phenomenon known as otoacoustic emissions (OAEs). The contraction of the outer hair cells in response to sound causes the cochlea itself to vibrate, in effect generating its own sound, like a faint echo of the original sound stimulus. Humans typically cannot hear this sound, because it is drowned out by ambient sound, but the phenomenon of OAEs is used to screen for hearing problems in newborns (see below).

There are many similarities between the visual and auditory systems in how they transmit nerve impulses to the brain. When hair cells (especially inner hair cells) of the cochlea are excited by sound, they stimulate nerve impulses in ganglia cells of the auditory nerve (analogous ganglia cells are located in the retina in the visual system). Most of these impulses cross over to the opposite side of the brainstem and are transmitted through several way stations to the thalamus, the hub of sensory information, and arrive finally at the primary auditory cortex. Just as spatial information is retained in the transmission of visual information from the retina to the visual cortex, the frequency-specific (tonotopic) cochlear “sound map” of the world is faithfully reproduced at each level of the auditory nervous system.

Further processing of auditory information in the cortex is unique in humans because of the requirements of language. The human brain is especially effective at processing the subtle phonetic distinctions in speech, and the cortex is designed to support both the processing of phonemes (the basis of comprehension) and the encoding of phonemes (the basis of speech). As with processing in the visual cortex, there is a dorsal pathway, which subserves speech production, and a ventral pathway, which promotes language comprehension (Hickok, 2012; Hickok & Poeppel, 2007).

Development of Hearing

In the human embryo, the structures of the middle ear and cochlea are fully formed by 15 weeks’ gestation

(the beginning of the second trimester). By 20 weeks’ gestation, these structures are individually capable of responding to sound in the intrauterine environment and have formed connections to the ganglion cells of the auditory nerve and to the nuclei in the brainstem. By 25 to 26 weeks’ gestation, a loud noise *in utero* can produce changes in fetal heart rate and breathing patterns. By 28 to 30 weeks’ gestation (the beginning of the third trimester) the entire auditory system comes “online.” All of the neural connections from the cochlea to the temporal lobe of the cortex become active, and unborn infants begin to show behavioral responses to sound. It is at this stage that pregnant mothers may notice their infants moving in response to loud sounds in the external environment.

It is also at this stage (between 28 and 30 weeks’ gestation) that exposure to sounds in the intrauterine environment allows the cochlea to begin fine-tuning its response to different frequencies of sound; this process is known as **tonotopic tuning**. This process allows individual hair cells (especially the inner hair cells) to become exquisitely sensitive to specific sound frequencies. By the end of this process, adjacent hair cells in the cochlea differ in their characteristic or prime frequency response by only 0.2% (or one-thirtieth of the difference between adjacent piano keys; Graven & Browne, 2008). Because the amniotic fluid that surrounds the unborn infant preferentially transmits lower frequency sounds, the cochlea becomes tonotopically attuned to lower frequency sounds first and to higher frequency sounds after the infant is born. After 32 weeks’ gestation, unborn infants can recognize specific sounds, including and especially their mothers’ voices, and also become aware of specific melodies, which they will show a preference for after they are born (Graven & Browne, 2008; Moon & Fifer, 2000).

In contrast to vision, which requires exposure to visual experiences and stimuli *after* birth for normal development, hearing requires exposure to sound, and to the right types of sound, *before* birth (beginning at 28 weeks’ gestation). It is especially important for unborn infants to be exposed to environmental sounds (particularly voices and music) that allow them to develop an early sensitivity to phonemes. By contrast, very loud sounds, especially those above 60 dB, can be damaging to the delicate hairs cells of the developing cochlea. For this reason, placing headphones on a pregnant mother’s abdomen to play music to an unborn infant is *not* advisable, as the loudness of this mode of sound delivery may easily be underestimated (Box 7.2).

Especially concerning is the potential impact of noise on children born prematurely. These children, some of whom are born as early as 23 weeks’ gestational age, are exposed to a cacophony of sounds

BOX 7.2 EVIDENCE-BASED PRACTICE**Noise in the Newborn Intensive Care Unit**

Based on years of research on the deleterious effects of exposure to loud noise to both the fetus and the premature infant, a multidisciplinary group of clinicians and researchers known as the Sound Study Group developed the following recommendations (Graven, 2000; Krueger, Horesh, & Crossland, 2012; Philbin, Robertson, & Hall, 2008).

Application to Practice*For the fetus:*

- Women should avoid prolonged exposure to low-frequency sound (sound below 250 Hz) above 65 dB during pregnancy.
- Sound devices such as earphones should not be placed directly on a pregnant woman's abdomen.
- Special programs to supplement the fetal auditory experience (playing recorded music) are not recommended as the voice of the mother and normal sounds of the mother's body are sufficient for normal auditory development.

For the preterm infant:

- The hourly Leq (the equivalent steady noise level of an hour of sound, if noise levels were constant instead of varying) should not exceed 50 dB.
- The hourly L10 (the measured decibel level exceeded for 10% of an hour) should not exceed 55 dB.
- The 1-second Lmax (the highest decibel level exceeded for at least one-twentieth of a second in an hour) should not exceed 70 dB.
- Earphones and similar devices should not be placed on an infant's ears at any time.

Studies indicate that implementation of these recommendations in newborn intensive care units (NICUs) has been problematic. In one study, average noise levels measured in a NICU during the day and night ranged from 50 to 90 dB, with the highest measured Leq at 85.4 dB in a centrally located area of the unit (Matook, Sullivan, Salisbury, Miller, & Lester, 2010).

and loud noises in the acoustically challenging environment of the neonatal intensive care nursery. Recommendations have been developed for managing environmental noise in the classic multibed newborn intensive care unit (NICU), but significant concerns remain about implementation of these recommendations and about the long-term disabling effects of noise on former premature infants who already have many other risk factors for adverse developmental outcomes (see Chapter 5; Krueger et al., 2012). As a result, recently constructed NICUs have single-bed rooms where environmental noises can be better controlled.

The Auditory System and Language

The auditory system in humans is uniquely designed to support language processing and production. As mentioned previously, human infants are born with the ability to distinguish all of the phonemes represented by all languages (Jusczyk, 2002). This ability is promoted in part by the process of tonotopic tuning

in the late prenatal and early postnatal periods, which makes the cochlea exquisitely sensitive to subtle differences in pitch, and by the unique organizational characteristics of the human cortex. Children 6 months of age typically show equal interest in and sensitivity to the sounds of all languages, but by 9 months, they begin to show a preference for the sounds, intonations, and rhythms of their native language. By 3 years of age, this preference is firmly entrenched. This is one of the reasons that developing fluency in a second language is much easier for a child exposed to the phonemic environment of that language prior to 3 years.

In a broader sense, early childhood represents a sensitive and critical period for language development. Children with a significant hearing loss are at a great risk for impairments of speech and language. Research shows that identifying and treating hearing problems as early as possible results in the best outcomes for language development. In particular, children who are born with significant hearing loss have the best language outcomes if interventions begin prior

to 6 months of age (Centers for Disease Control and Prevention, 2017; Choo & Meinzen-Derr, 2010; Grindle, 2014; also see Chapter 17 for detailed information about speech and language disorders).

Types of Hearing Loss

There are several types of hearing loss (please see Chapter 26 for a detailed discussion). **Conductive hearing loss** (problems with the middle ear) is the most common type. It tends to be associated with minimal to moderate degrees of hearing loss and is often temporary. Because this type of hearing loss is often associated with otitis media, medical intervention (antibiotic therapy) or surgery (pressure equalizer tube placement) is often employed in its treatment.

By contrast, **sensorineural hearing loss** (resulting from abnormalities in the cochlea or auditory nerve) is often congenital. It may have a genetic origin and be progressive in nature. While less common than conductive hearing loss (occurring in about 1 out of 1,000 newborns), it is more often associated with severe to profound hearing loss. Interventions include the use of hearing aids; special education and targeted therapy; and, in some cases, cochlear implants. Although any degree of hearing loss can be associated with negative language outcomes, early identification of hearing loss is an especially high priority and is the primary target of screening programs in infants and young children (Centers for Disease Control and Prevention, 2017; Grindle, 2014).

Screening for Hearing Problems

Universal newborn hearing screening (UNHS) has now become the norm in the United States. This has revolutionized the identification of children with hearing loss, especially those with severe to profound sensorineural hearing loss. As of 2014, 97% of newborns in the United States were being screened for hearing loss (Centers for Disease Control and Prevention, 2017). Following the implementation of newborn screening, the mean age of identification for children with hearing loss has dropped from 2.5 years to 2 to 3 months (Harrison, Roush, & Wallace, 2003). The primary goals of UNHS are the following:

- Screen all infants by 1 month of age
- Identify all children with permanent hearing loss by 3 months of age
- Initiate appropriate interventions for hearing loss by 6 months of age

- Establish a medical home (see Chapter 30) for children with hearing loss
- Collect data and track progress with screening as a public health initiative

The Centers for Disease Control and Prevention provide an excellent resource for information related to hearing loss and newborn screening, including up-to-date statistics on the progress of UNHS at <http://www.cdc.gov/ncbddd/hearingloss/data.html>. Infants at increased risk of delayed onset of hearing loss (e.g., premature infants and those exposed to intrauterine infections) should be followed even if they pass newborn hearing testing.

Screening Methods

Currently two methods are used to screen hearing in newborns, **otoacoustic emission** (OAE) testing and **auditory brainstem response** (ABR) testing. OAE testing is based on the fact that the cochlea generates a subtle but detectable “echo” in response to an acoustic stimulus (based on the action of the cochlear amplification system; see previous discussion). The OAE device is inserted into the ear canal of the newborn and emits a continuous tone; a microphone picks up the cochlear response to this tone. An advantage of OAE testing is that it is easy to perform and can be done in a quiet, awake infant. It also requires less training to use. Disadvantages include difficulties in obtaining an accurate result in children with external or middle ear problems (e.g., earwax) and a fairly high rate of false-positive results (children having an abnormal test who actually have normal hearing). OAE is also based on the assumption that most causes of sensorineural loss (SNHL) are due to cochlear dysfunction, so it will miss those rarer instances when SNHL is due to auditory nerve dysfunction.

ABR testing is based on the fact that, when the auditory system is intact, acoustic stimuli presented to the ear will generate nerve impulses in the auditory nerve and brain that can be detected by electrodes placed on the scalp. There are both screening (automated) and full (nonautomated or diagnostic) versions of the test. The screening version is used for initial testing. A device is inserted into the ear canal that generates either high-frequency clicks or frequency-specific tones. Electrodes placed at strategic locations on the newborn’s head pick up the signals generated as they progress through the nervous system. The advantages of the ABR are that it is less prone to interference from problems in the external or middle ears, has a lower false-positive rate than the OAE, and will detect SNHL due to both cochlear and auditory nerve abnormalities.

However, the ABR is more difficult to perform, requires more training to administer, and requires a quiet or sleeping infant (Grindle, 2014).

Most newborn screening programs for hearing loss employ a two-step process. Children who fail the initial screen (whether it is an OAE or an ABR) will typically be retested, often using a full ABR test. As mentioned previously, one of the goals of UNHS is to identify all children with congenital hearing loss by 3 months of age. As of 2014, although 97% of newborns were screened, of those who failed the initial screening, only 71% were identified as having or not having hearing loss by 3 months of age. This highlights the challenge of ensuring adequate follow-up for children with potential hearing loss (Centers for Disease Control and Prevention, 2017).

Congenital Cytomegalovirus Infection and Screening

Although the most common cause of congenital sensorineural hearing loss is genetic, the second most common cause is congenital cytomegalovirus (CMV) infection (see Chapter 26). CMV infection can be diagnosed by detection of the virus in saliva or urine, but because acquired infections are so common, it is imperative to test suspected infants in the newborn period to ensure an accurate diagnosis. Current recommendations include testing all children who have signs of CMV infection and all children who have failed newborn hearing screening. As of 2018, whether or not all newborns should be screened for congenital CMV is a point of active discussion since many cases that cause sensorineural hearing loss are asymptomatic. Identifying congenital CMV is especially important in light of reports that treatment with antiviral drugs may prevent SNHL and perhaps reverse the progression of SNHL in affected children (Choo & Meinzen-Derr, 2010; Oliver et al., 2009).

THE WORLD WE FEEL

When thinking about senses, the ones that tend to come to mind first are those that help individuals engage the world outside and around them; vision and hearing have particular primacy in this view of the senses. However, “below the hood” there exist myriad, inwardly directed sensory systems that help to sense and regulate the world. In many instances, these senses are not “sensed” in the usual meaning of the term. They do provide feedback about the internal state of an individual’s body but often at an unconscious level. These internal sensors are especially critical to the regulation

of movement and provide an awareness of the position of our bodies in space. These sensory systems are a critical part of the complex motor planning and control apparatus known as the **somatosensory system**.

The Somatosensory System

Taken together, the somatosensory system refers to all of the physiological systems that provide feedback about the internal states of the body to the central nervous system (CNS). The CNS is organized hierarchically: sensory data from the muscles, tendons, joints, and skin are fed back to the spinal cord and brainstem, where they are processed locally and provide direct feedback to reflex mechanisms that support rapid moment-by-moment motor control. Sensory data are further processed in the thalamus (the “Grand Central Station” of sensory processing at the heart of the brain, referred to in the previous discussions on vision and hearing) and ultimately arrive at the somatosensory cortex located in the parietal lobes of the brain (see Chapter 8).

Proprioception **Proprioception** refers to those components of the somatosensory system that provide feedback regarding the states of muscles, tendons, and joints. Proprioception, together with information from sensors in our skin (cutaneous sensation) and in our inner ear (vestibular sense or balance), provides individuals with “body awareness” and a sense of the position of the body in space.

Muscle Spindles Muscle spindles are special sensors located in all of the muscles of the body. They are also referred to as stretch receptors, because their primary function is to sense the state of stretch in muscles from moment to moment. Rapid stretching of muscles causes the muscle spindles to fire, and nerve impulses feed back to the spinal cord and trigger motor neurons that supply the same muscles to cause a compensatory muscular contraction. This is the basis of the familiar knee-jerk reflex (Bear et al., 2016; Shumway-Cook & Woollacott, 2017).

Golgi Tendon Organs Golgi tendon organs (GTOs) are located at the junction of muscles and their tendons; they are highly sensitive to changes in tension that result from muscle stretch or contraction. In contrast to muscle spindles (which are arranged in parallel with muscle fibers), GTOs (situated between muscles and the bones to which they are attached) are arranged in series with muscle fibers. Whereas muscle spindles provide feedback about muscle length, GTOs

provide information about muscle tension. When a muscle tendon unit is under increased tension, GTOs send nerve impulses back to the spinal cord that result in inhibition of contraction of the same muscle. This allows for finely-graded movement and is thought to be especially important in the manipulation of fragile objects that must be held with steady, but not excessive pressure (Bear et al., 2016; Shumway-Cook & Woollacott, 2017).

Joint Receptors Several different sensor types are present in the joints of the body, some of which are similar to GTOs and others of which are similar to mechanoreceptors (pressure sensors) in the skin. Joint receptors are especially important in contributing to our awareness of joint angle, an important aspect of body awareness (Shumway-Cook & Woollacott, 2017).

Cutaneous Receptors The skin has an array of receptors that are sensitive to a wide variety of stimuli. Pain receptors (also called nociceptors) are sensitive to sources of mechanical and thermal energy that could cause tissue damage. Touch receptors (which include a variety of mechanoreceptors, or sensors that respond to mechanical changes in the skin) are sensitive to wide variations of pressure, vibration, rubbing, pinching, and pricking. High concentrations of particular types of touch receptors are present in our hands, especially in our fingertips, providing critical sensory feedback for fine motor control. Considered globally, cutaneous receptors throughout the body provide a crucial component of body awareness by furnishing the CNS with data regarding the state of our “interface” with the outside world (Bear et al., 2016).

The Vestibular System The **vestibular apparatus** (VA), located in the inner ear, assists our sense of balance (see Figure 7.7). The vestibular apparatus has two main components, the semicircular canals and the otolith organs. The **semicircular canals** consist of fluid-filled tubular structures that form three loops arranged at right angles to each other. The fluid moves in response to angular acceleration of the head (as when a child spins in circles) and provides the CNS with feedback regarding rotational movements of the head. The **otolith organs** (the utricle and the saccule) sit at the base of the vestibular apparatus near the convergence of the semicircular canals. These organs contain calcium carbonate crystals (called otoliths) that shift position with changes in head tilt. They are also sensitive to changes in linear acceleration (forward and backward movement) of the head. The main

function of the otolith organs is to provide the CNS with feedback regarding the position of the head with respect to gravity (Bear et al., 2016; Shumway-Cook & Woollacott, 2017).

SENSORY INTEGRATION AND MOTOR CONTROL

Like the studio musician who cannot play his instrument without being able to hear feedback of his own performance, human beings cannot control their own movements and adaptive responses without constant feedback from every component of the sensory system. While the somatosensory system is especially important to motor control, our other senses (especially vision and hearing) also make an important contribution to the process. The idea of **sensory integration** arises from the recognition that the brain must perform an astonishing feat of computational analysis on a continuous stream of sensory and motor data to allow for even the simplest of movements.

■ ■ ■ CASE STUDY

Casey is a 10-year-old boy who was diagnosed with autism spectrum disorder (see Chapter 18) when he was 7 years old. Although his biggest challenges relate to his social skills and behavior, he has also struggled with “clumsiness,” lack of coordination, and “sensory issues.” The developmental pediatrician who diagnosed him with autism also diagnosed developmental coordination disorder and made reference to problems with “sensory integration” in her original diagnostic report.

In particular, Casey had severe aversions to loud noises, bright lights, strong odors, and an array of tactile sensations as a toddler and preschooler. He abhorred having his hair washed, would only take baths in lukewarm water, hated wearing socks, and preferred to be naked whenever that was allowed. Paradoxically, he seemed to be relatively insensitive to pain, and on one particular occasion, after a bad fall, he made no complaint of a badly swollen toe that was later found to be broken. As he got older, these “sensory issues” have improved, and he has learned to cope with the ones that have persisted. For example, he is allowed to wear headphones when his school has a fire drill, as sensitivity to loud noises is still a problem for him.

When a child like Casey is diagnosed with a developmental coordination disorder, clinicians must consider whether his physical awkwardness results from a primary problem with motor output or a problem with the integration of sensory data with the motor control system.

Dunn's Model of Sensory Processing

The concept of sensory integration recognizes that while sensory data are registered in multiple modalities (e.g., vision, hearing, touch, and balance; see Table 7.1), these divergent sources of information from the outside world and from within the body must be combined in order to provide for the possibility of a coherent and adaptive behavioral response. Theoretical approaches to sensory integration therefore take a unified, "trans-modal" approach to sensory data.

Dunn's Model of Sensory Processing (Dunn, 1997) has been particularly influential in this regard (Table 7.4). The model is based on a detailed analysis of the sensory profiles (see below) of typically developing children, and it characterizes individuals based on their sensitivity to sensory stimuli (or neurologic threshold for reacting to the stimuli) and their manner of responding to these stimuli. Children who have a *high sensory threshold* tend to have a low sensitivity (are hyposensitive) to sensory stimuli. For example, children with a high sensory threshold may seem unreactive to sounds that would gain the attention of most children. By contrast, children with *low sensory threshold* are overly sensitive (hypersensitive) to sensory stimuli. Sounds that might not be noticed by most children might be distracting or disturbing to these children.

Children also differ in their behavioral responses to stimuli. Those who are *passive responders* tend to be underreactive (hyporeactive) to sensory stimuli. Passive responders who are also hyposensitive (with a high sensory threshold) are said to have *low registration*. Children with low registration may seem insensitive to injury and may be surprisingly slow to respond to a cut or bruise that would elicit a dramatic response from most children. Passive responders who are hypersensitive (with a low sensory threshold) are said to be *sensory sensitive*. Sensory sensitive children might be

bothered by being hugged but don't respond actively to their discomfort.

Children who are *active responders*, by contrast, tend to be overreactive (hyperreactive) to sensory stimuli. Active responders who are hyposensitive (with a high sensory threshold) are said to be *sensory seeking*. Sensory-seeking children may, for example, have a strong need for oral stimulation and will compulsively seek out things to chew, including nonfood items. Active responders who are hypersensitive (with a low sensory threshold) are said to be *sensory avoidant*. Sensory avoidant children will go out of their way to withdraw from situations that are overstimulating to them.

Screening and Assessment

In contrast to screening methods employed to identify problems with vision and hearing, which rely on specific, discrete screening methods and tools, screening and assessment of sensory processing involves a complex set of clinical processes that address all levels of sensory processing, from the registration of sensory data to adaptive behavioral responses in specific settings. These clinical processes are most often carried out by an occupational therapist (Box 7.3).

A number of specific screening tools are commonly employed in the evaluation of sensory processing. Two frequently used measures are the Sensory Profile-2 (Dunn, 2014) and the Sensory Processing Measure (Miller-Kuhaneck, Henry, Glennon, & Mu, 2007). The Sensory Profile-2 is keyed to Dunn's Model of Sensory Integration and provides a means of categorizing a child as being low registering, sensory sensitive, sensory seeking, or sensory avoidant. Several versions have been developed for different age groups for birth to adulthood. The Sensory Processing Measure (for ages 3 to 12 years) can assess sensory vulnerabilities in multiple settings and includes parent and teacher rating scales.

Table 7.4. Dunn's Model of Sensory Processing (Dunn, 1997)

		Continuum of behavioral response	
		Passive (hyporeactive)	Active (hyperreactive)
Continuum of neurologic/sensory registration	High threshold (hypo-sensitive)	<i>Low registration</i> • Less sensitive to sensory stimuli • Low level of reactivity manifests as slow or absent response to sensory stimuli	<i>Sensory seeking</i> • Less sensitive to sensory stimuli • High level of reactivity manifests as effort to access/experience (seek-out) sensory stimuli
	Low threshold (hyper-sensitive)	<i>Sensory sensitive</i> • More sensitive to sensory stimuli • Low level of reactivity manifests as distraction and discomfort	<i>Sensory avoidant</i> • More sensitive to sensory stimuli • High level of reactivity manifests as avoidance of offending stimuli

BOX 7.3 INTERDISCIPLINARY CARE**Sensory Integration and the Role of the Occupational Therapist**

At its heart, occupational therapy is devoted to helping people adapt to and function optimally in their real-life settings. Occupational therapists (OTs) who work with children focus especially on helping them to develop functional independence with activities of daily living at home and to develop skills that support academic growth and classroom adaptation at school.

In these settings and in others, children with sensory challenges benefit from working with OTs in several ways. OTs provide an in-depth assessment of a child's profile of sensory sensitivities, needs, and responses, employing diagnostic tools and interpreting the results of these assessments in light of a child's specific circumstances. OTs often work with families and teachers to develop accommodations to the sensory features of the home and school environment. For example, a child with sensitivities to loud noise might be provided with noise cancelling headphones. OT-designed "sensory diets" offer a schedule of accommodations in specific settings (such as school) to help a child cope with the challenges of difficult sensory environments and complex schedules.

Direct interventions are also employed. These include sensory integration therapy (based on the work of Dr. A. Jane Ayres) and a variety of sensory based therapies that focus on providing children with coping strategies for dealing with an often unpredictable sensory environment. Some interventions use targeted sensory input (vestibular, proprioceptive, auditory, and tactile) by means of special techniques such as brushing, the application of "deep pressure," the use of weighted blankets and vests, and the use of swings (to provide vestibular input) in order to influence or modulate a child's pattern of sensory responsiveness. In each instance, the OT's therapy is tailored to a child's specific needs and circumstances, with the overall goal of improving functional adaptation and independence.

Occupation therapy researchers are working to clarify the efficacy of these various interventions. For example, a systematic review of research on the efficacy of sensory integration therapy in children found evidence of improvements in function and behavior across several domains but also recognized variability in the approaches employed in various studies and endorsed the need for further research (May-Benson & Koomar, 2010).

Sensory Processing Disorders

In the 1970s, A. Jean Ayres, PhD, proposed that some children may have abnormalities of these sensory integration processes that could lead not only to problems with motor control, but also to difficulties with other aspects of development, learning, and emotional regulation (Ayres, Robbins, & Pediatric Therapy Network, 2005). This led to the development of the concept of **sensory processing disorders**.

More recently, a classification system for sensory processing disorders has been proposed (Miller, Anzalone, Lane, Cermak, & Osten, 2007). Three types of sensory processing disorders are suggested:

- Sensory modulation disorder (subdivided into over-responsive, underresponsive, and sensory-seeking subtypes)
- Sensory discrimination disorder (difficult distinguishing among sensory stimuli)

- Sensory-based motor disability (subdivided into postural disorder and dyspraxia)

Although the therapeutic interventions for sensory processing disorders and the diagnosis itself have become widely employed, neither have been universally accepted. In the most recent edition of the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (American Psychiatric Association, 2013), sensory disturbances have been recognized as a diagnostic component of autism spectrum disorder (see Chapter 18), but sensory processing disorders were not accepted as a separate diagnosis, pending further research (Zimmer & Desch, 2012).

SUMMARY

- The senses provide individuals with a means to adapt to the world around them and regulate their responses to that world.

CHAPTER 8

The Brain and Nervous System

Joseph Scafidi and Andrea Gropman

Upon completion of this chapter, the reader will

- Understand the anatomical structures of the brain and their purposes
- Know about the roles played by neurons, oligodendrocytes, and astrocytes in the function of the central nervous system
- Discover how neural stem cells develop into neurons and oligodendrocytes in the prenatal and postnatal brain
- Be able to explain the origin and function of cerebrospinal fluid and its associated blockage in hydrocephalus
- Understand current imaging technologies that help us evaluate the central nervous system

The **central nervous system** (CNS) is an incredibly complex system that is comprised of the brain and spinal cord. The CNS is responsible for receiving and processing sensory information, movement data, cognitive information, social behaviors, and other interactions with the surrounding world. An impairment of any part of this complex system reduces the ability of the individual to adapt to the environment, and it can lead to disorders as diverse as learning disabilities, **autism spectrum disorder** (ASD), **cerebral palsy**, and **epilepsy**. This chapter provides an overview of the interrelationships among the individual elements of the CNS and the peripheral nervous system (PNS). It also describes examples of CNS and PNS dysfunction and their effects on a child.

■ ■ ■ CASE STUDY

Thomas, born after a 41-week pregnancy, developed intermittent tonic-clonic activity of the right arm and leg at 18 hours of life. The duration of these events was between 1–3 minutes. In between, Thomas was noted to have less movement of the right arm and leg than the left. He was immediately transferred to the neonatal intensive care unit for suspicion of seizures, and neurology was consulted. A neurological exam revealed mild facial asymmetry, decreased motor strength of the right arm and legs, and **hyporeflexia** (decreased deep tendon reflexes) on the right side. Thomas was administered the medication phenobarbital to stop the seizures. An electroencephalogram (EEG) captured one of the events prior to phenobarbital

administration and showed seizure activity emanating from the left central-temporal and parietal regions of the cortex. During periods when there were no seizure events, there was slowing of the EEG background activity in this region of the brain. Phenobarbital levels were adjusted to prevent further seizures. Magnetic resonance imaging (MRI) revealed a middle cerebral artery distribution acute stroke on the left affecting the frontal-parietal region (Figure 8.1). Thomas remained on phenobarbital for 1 week and then was weaned off of this medication.

A subsequent neurologic examination at 1 year of age revealed almost symmetric strength of his arm and leg but some **hyperreflexia** (increased deep tendon reflexes) on the right. It was noted that when reaching for objects or standing, Thomas favored using his left hand. It was also noted that age-appropriate fine motor skills were limited on the right compared with the left side. No delays were noted in his language, and no further seizures had been noted by the family. In summary, Thomas' diagnosis is neonatal seizures as a result of an acute left-sided stroke. Phenobarbital was administered to stop the seizures during the acute period and was stopped to prevent long-term side effects of medication. His outcome should be good, although he may retain subtle weakness on the right side of his body as a consequence of the stroke. At 2 years of age, Thomas will likely receive a diagnosis of right hemiplegic cerebral palsy.

Thought Questions:

What are the six main structures of the central nervous system? What are the major components of the peripheral nervous system and some disorders associated with it? What are the different diagnostic techniques for evaluating neurodevelopmental disorders? Compare and contrast the different diagnostic techniques for evaluating the central nervous system.

THE BRAIN AND SPINAL CORD

The brain and the spinal cord comprise the mature CNS and have six main structures: 1) the cerebral hemispheres, 2) basal ganglia, 3) thalamus, 4) brainstem, 5) cerebellum, and 6) spinal cord (Crossman & Neary, 2015).

The Cerebral Hemispheres

During embryonic development, the CNS develops from a layer of ectodermal cells that folds over and becomes the neural tube. In turn, the neural tube develops several swellings that eventually develop into the brain and spinal cord, and the cavity within the neural tube develops into the ventricles (see Chapter 6). The first bulge is the **prosencephalon**, which becomes the **telencephalon** and **diencephalon** (thalamus and hypothalamus). The telencephalon consists of the cerebral cortex, subcortical white matter (where the “wiring” of the brain is found), and deep masses of gray matter collectively called the **basal ganglia** (containing specialized groupings of neurons). Within each hemisphere, there is a fluid-filled cavity called the **lateral ventricle**. The main connection between the two hemispheres is a large band of axonal fibers called the **corpus callosum** that permits the exchange of information between the two hemispheres (Figure 8.2A and 8.2B). There are genetic and environmental factors that may interfere with the normal formation of the corpus callosum and, in the most severe cases, result in its complete lack of development (termed **agenesis** of the corpus callosum) (Palmer & Mowat, 2014). The importance of this exchange of information is highlighted by the results of a surgical procedure called a **corpus callosotomy**. In this operation, all or part of the corpus callosum is cut in an effort to control a severe seizure

Figure 8.1. A full-term neonate that presented with neonatal seizures noted on the right side of the body. Magnetic resonance imaging on the third day of life revealed an acute left middle cerebral artery distribution stroke. The arrow on the left image points to the region where ischemia was present. Upon exam, the patient had evidence of right-sided body asymmetries.

Figure 8.2. A) Sagittal view of the brain showing the component elements: cerebral hemispheres, diencephalon, cerebellum, brainstem, and spinal cord. B) Lateral view of brain by magnetic resonance imaging scan. Note the excellent reproduction of the structures of the brain. C) Side view of the left hemisphere. The cortex is divided into four lobes: frontal, parietal, temporal, and occipital. The motor strip, lying at the back of the frontal lobe, is highlighted. It initiates voluntary movement.

disorder (Graham et al., 2016). It has proven quite effective in decreasing the spread of seizure activity from one hemisphere to the other. In some adults, however, it has resulted in a disconnection syndrome and declines in language, visual-perceptual skills, and manual dexterity. This is the result of a decreased ability of the hemispheres to communicate with each other (Malmgren et al., 2015).

In early fetal life, the surface of the cerebral hemisphere is smooth. As the brain's complexity increases during the third trimester, involutions called **fissures**

and **sulci** appear. Fissures, which are deeper than sulci, are first visible during fetal development and divide each hemisphere into four functional areas or lobes. The frontal lobe occupies the anterior third of the hemisphere; the parietal lobe sits in the middle-upper part of the hemisphere; the temporal lobe is in the middle-lower region; and the occipital lobe takes up the posterior quarter of each hemisphere (Figure 8.2C). The sulci are smaller involutions within each lobe, and the regions between the sulci are called convolutions or **gyri** (Figure 8.2A). Some gyri vary little in location and contour from one person to another, whereas others vary considerably. Sulci and gyri increase the surface area of the brain and permit additional growth within the limited space of the brain cavity.

The surface of the cerebral hemisphere, called the **cortex**, consists of gray matter. It is composed principally of **neurons** (nerve cell bodies) and **glia** (supporting cells). Below this gray matter lie the nerve fibers (**axons**) that are insulated and comprise the white matter. The function of the cerebral cortex is to initiate motion and thought processes, and to process sensory input. The cortex of each lobe is responsible for specific activities or functions, outlined in more detail below.

The Frontal Lobe The frontal lobe controls voluntary motor activity and makes significant contributions to cognition and executive function (Burgess & Stuss, 2017; Nowrangi et al., 2014). It plays an important role in attention, impulse control, and emotion. Impaired frontal lobe function is responsible for conditions such as intellectual disability, attention-deficit/hyperactivity disorder (ADHD), and certain genetic disorders (e.g., autosomal dominant nocturnal frontal lobe epilepsy). The anterior cingulate cortex and fronto-insular cortex, in particular, are connected to process information across a variety of domains, including those related to attention, emotion, and effortful tasks (Craig, 2009; Engstrom, Karlsson, Landtblom, & Craig, 2015).

Within the frontal lobe the different regions of the body are represented topographically along a strip called the primary motor cortex (Brodmann area 4). The tongue and larynx, or voice box, are controlled from the lowest point followed in an upward sequence by the face, hand, arm, trunk, thigh, and foot (Figure 8.3). The tongue, larynx, and hand occupy a particularly large area along this strip because more neurons are necessary due to the complexity of speech and fine motor activity.

A nerve impulse initiated in the motor strip passes down the **pyramidal tract** (also called the **corticospinal pathway**) that connects the cortex with the spinal cord. Reaching the spinal cord, the impulse jumps across a

Figure 8.3. The motor strip. The cartoon figure represents body parts at various points on the strip. Note that the areas representing facial and hand muscles are very large. This is because of the intricate control necessary for speech and fine motor coordination. A cross-section of the motor strip is shown to the right.

synapse (junction between two nerve cells) to an anterior horn cell in the gray matter section of the spinal cord. This neuron relays the transmission via its axon to a peripheral nerve that connects to an appropriate muscle. The muscle subsequently contracts in response to the original signal from the motor strip in the cortex. In **spinal muscular atrophy** (Werdnig-Hoffman disease), the motor neuron dies during childhood, resulting in **hypotonia** (low muscle tone) and weakness (Shababi, Lorson, & Rudnik-Schoneborn, 2014; see Chapter 9).

Conversely, if the motor cortex or the pyramidal tract is damaged, increased tone in the form of spasticity results. In spasticity, the underlying involuntary muscle contractions controlled by the brainstem and spinal cord are no longer inhibited by pyramidal tract activity. As a result, voluntary movement becomes less fluid and muscle control is more difficult, as seen in cerebral palsy and other movement disorders (see Chapter 21). Therapeutic approaches to spasticity focus on manipulating neurotransmitters to reduce tone. For example, the drug baclofen, which decreases spasticity by increasing the activity of gamma-aminobutyric acid (GABA), an inhibitory neurotransmitter, can be administered orally or into the spinal fluid using an implantable pump in individuals with cerebral palsy (Hasnat & Rice, 2015; He et al., 2014). Damage to the motor cortex can also lead to focal-onset seizures, as occurred with Thomas (see Chapter 22).

The frontal lobe is also important in abstract thinking. Via functional imaging techniques, the frontal lobe has been identified as the origin of executive function (Burgess & Stuss, 2017). This high-level abstract thinking is the planner and organizer for future activities. Children with autism, ADHD, and learning disabilities show deficiencies in executive function (Bos et al., 2017; Rubia et al., 2011; see Chapters 18–20).

Broca's area (Figure 8.4), the center for expressive language, typically resides in the left frontal lobe,

anterior to the motor strip (see Chapter 17). The location can vary, particularly in children who are left-handed, have epilepsy, or have prior destructive lesions such as tumors or stroke (Avramescu-Murphy et al., 2017; Benjamin et al., 2017; Gaillard et al., 2011; Steinberg, Ratner, Gaillard, & Berl, 2013).

The Parietal Lobe Touch, pain, vibration, **proprioception** (the ability to sense the position, location, orientation, and movement of body parts), and temperature sensation are all processed within the parietal lobe. In addition, the parietal lobe contributes to the integration of stimuli from different regions, providing the ability to create a complete "picture." The primary sensory cortex (Brodmann area 3,1,2) is located in the postcentral gyrus of the brain and receives all sensory information in a **somatotopical** organization (point-for-point correspondence of an area of the body to a specific area in the brain) from the opposite side of the body. Information to the primary somatosensory cortex arrives from the **thalamus**. Injury to the thalamus

Figure 8.4. An adult neuropathological model of language. Sounds are received in Wernicke's area and passed on to Broca's area via nerve fibers of the arcuate fasciculus. Expressive language is formed here, and the motor cortex is then stimulated to produce speech.

(e.g., by a stroke) may produce **paresthesias** (numbness with a pins-and-needles sensation) on the opposite side of the body. A destructive lesion (e.g., a tumor or hemorrhage) in this area impairs sensation, including difficulty localizing painful stimuli or measuring their intensity. Although the primary visual cortex is in the occipital lobe, some higher levels of visual processing take place in the parietal lobe. There is evidence that the visual-perceptual problems experienced by children with learning disabilities and the difficulties in performing fine motor tasks found in children with ADHD may be related to parietal region abnormalities (Cubillo et al., 2010; Schulz et al., 2017).

The Temporal Lobe The temporal lobe is primarily involved in communication and sensation. The dominant hemisphere (the left side in more than 90% of people) is responsible for comprehending speech as well as contributing to the memory of auditory and visual experiences (Gaillard et al., 2011). It receives input from each ear, with somatotopical projection of the **cochlea** (the spiral-shaped cavity of the inner ear that resembles a snail shell and contains nerve endings essential for hearing) upon the acoustic area of the temporal lobe. Wernicke's area, the receptive language center, is found in the superior temporal gyrus. As with Broca's area, it is most commonly found on the left side, but its location can vary (Berl et al., 2014).

Within the base of each temporal lobe rests two structures, the **hippocampus** and **amygdala**, which serve special cognitive functions. The hippocampus plays an important role in memory and allows for learning of new information. The amygdala is involved in sensory processing and emotions and is part of the general-purpose "fight-or-flight" defense response control system.

Both the amygdala and hippocampus show structural abnormalities in autism, with the degree of abnormality being linked to the severity of impairment (Barnea-Goraly et al., 2014; Dziobek, Bahnemann, Convit, & Heekeren, 2010; Kleinhans et al., 2010). It is unclear if alterations in the hippocampus are a cause or an effect of the disorder's symptomatology. Studies in both animals and humans suggest that the hippocampus can undergo dynamic changes as a result of experience, behavior, and exercise (Insausti, Cebada-Sánchez, & Marcos, 2010; Korol, Gold, & Scavuzzo, 2013).

In humans, the amygdala is associated with emotional and social functions. Recent use of functional MRI (fMRI) has demonstrated that the human brain is equipped with specialized circuits for discriminating facial emotions. In particular, the crucial involvement of the amygdala in emotional face processing has been demonstrated by a large number of studies comparing patients with damaged amygdala and unaffected

subjects (Damiano, Churches, Ring, & Baron-Cohen, 2011). Amygdala dysfunction has also been strongly implicated in the social deficits of autism as it is involved in the ability to read and relate to others' emotions.

Recent evidence suggests that several aspects of face processing are impaired in patients with autism (Damiano et al., 2011). The most reproducible features include atypical patterns of gaze processing, memory for facial identity, and recognition of the emotional content of facial expressions. Research studying face processing in autism focuses on impairments in a specific network of brain regions that are implicated in social cognition and face processing. These include the superior temporal sulcus (located in the temporal lobe), which plays a role in processing gaze and facial movements, and the fusiform face area (located on the ventral surface of the temporal lobe). It is not known how alterations in developmental processes and the role of experience interact during normal development and in autism to modify and influence this network.

Temporal lobe dysfunction can contribute to a number of disorders, the two most common being receptive **aphasia** and focal to bilateral seizures (Chatzikonstantinou, 2014; Mesulam et al., 2014). In receptive aphasia, the temporal lobe may have been damaged by a tumor, vascular insufficiency, or trauma. The individual is unable to understand spoken words but is able to speak, frequently in an unintelligible fashion. Individuals with focal seizures originating from the temporal lobe may initially experience a *déjà vu* or flashback phenomenon caused by stimulation of this brain area. The person may also have visual hallucinations, hear bizarre sounds, or smell unpleasant aromas, all of which emanate from the temporal lobe.

Treatment of refractory complex partial seizures may involve surgical removal of the seizure focus (Ravindra, Sweney, & Bollo, 2017). This surgery has been shown in adults to be superior to long-term antiepileptic drug use in terms of seizure control and quality of life (see Chapter 22). Although adults who undergo this neurosurgical procedure on the left side of the brain often sustain some language or memory loss, children appear less likely to experience this complication. This suggests that a child's brain is more flexible than an adult's, such that the nondominant hemisphere can take over some of the language functions of the damaged dominant area. In fact, children as old as 6 years have undergone total dominant **hemispherectomy** (removal of the left hemisphere for intractable generalized seizures with a left-sided focus) and have been able to recover speech function, presumably by incorporating other cortical locations in a new functional role (Bulteau et al., 2017; Johnston, 2009). This is a clear demonstration of the plasticity of the developing brain.

With hemispherectomy, the degree of language recovery varies according to the underlying cause of the seizure disorder (Bulteau et al., 2015; Ivanova et al., 2017).

In the temporal lobe, the primary auditory cortex receives input from both ears by way of the cochlear nerves via multiple synapses in the brainstem. Irritation of this cortex may cause a buzzing or roaring sensation in the ears. Because of the bilateral representation, unilateral damage does not result in deafness but may lead to a mild hearing loss. Bilateral lesions can result in a complete hearing loss.

The Occipital Lobe The primary visual receptive cortex is located in the occipital lobe. The right occipital lobe receives impulses from the right half of each **retina** (the nerve layer that lines the back of the eye, senses light, and creates impulses that travel through the optic nerve to the brain). This creates the left visual field, whereas the left visual cortex receives impulses from the left half of each retina (and creates the right visual field). The upper portion of this cortical area represents the upper half of each retina (the lower visual field), whereas the lower portion represents the lower half (the upper visual field). Irritation of the visual cortex can produce such visual hallucinations as flashes of light, rainbows, brilliant stars, or bright lines. Destructive lesions can cause defects in the visual fields on the opposite side without loss of central vision.

Visual stimuli are first interpreted in the visual-receptive area and then processed further in an adjacent part of the occipital lobe before being passed on to the temporal and parietal lobes (see Chapter 7). Here the identity of a viewed object and its location in space are further determined. In both the temporal and parietal lobes, the image is linked to what is heard and felt so that a proper interpretation can be made. Severe damage to the occipital region may cause **cortical visual impairment** (cortical blindness). In this condition, despite a normal visual apparatus and pathways leading toward the occipital lobe, the person is functionally blind.

Interconnections The white matter of the adult cerebral hemispheres contains nerve fibers of many sizes that are **myelinated** (sheathed by an insulating layer that increases the speed at which impulses are conducted). Some of these fibers serve to connect various regions of the brain. The most important of these interconnections is the corpus callosum, noted above (Figure 8.2A).

A second type of interconnection is formed by projection fibers that connect the cerebral cortex with lower portions of the brain or spinal cord. As an example, the **internal capsule** is a collection of fibers that projects from the cortex to the spinal cord; nerve

impulses carried by these fibers control distant muscles. Destructive lesions such as tumors or strokes may compress or otherwise compromise the internal capsule and the pyramidal (motor) tract it contains. This will result in **hemiplegia** (spasticity and weakness on the opposite side of the body).

Finally, association fibers connect various cortical areas within the same hemisphere. There are short association fibers, or U fibers, that connect adjacent gyri, while long association fibers connect more widely separated gyri.

The Basal Ganglia and Thalamus

Deep beneath the cortical surface resides the **diencephalon** (Figure 8.2A), which consists of the thalamus and **hypothalamus**. Adjacent to the diencephalon are the **basal ganglia** and related structures. In humans, this primitive part of the brain modulates instructions from the motor cortex in directing voluntary movements. In lower vertebrates it directly controls motor activity. Anatomically, the basal ganglia include the **caudate nucleus** and the **putamen** (together called the **corpus striatum**), the **globus pallidus**, and the other gray matter areas at the base of the forebrain. Together, the putamen and the globus pallidus form the **lentiform nucleus**. The caudate nucleus is separated from the lentiform nucleus and thalamus by the **internal capsule**. Functionally, these collections of neurons, together with their connections and neurotransmitters, form an associated motor system.

Damage to the basal ganglia produces various movement disorders. Although voluntary movement is still possible, involuntary jerking or twisting, referred to as **choreoathetosis**, may also occur. Alternatively, individuals may experience rigidity or **dystonic** posturing (involuntary contraction of muscles, forcing limbs into abnormal, sometimes painful postures). Children with perinatal brain injury involving the basal ganglia may have **dyskinetic cerebral palsy** (Monbaliu et al., 2017).

In the center of the brain is a crucial structure called the thalamus. Nearly all sensory input from throughout the body must first pass through the thalamus prior to reaching the appropriate region of the cortex. The thalamus is often referred to as a major relay station responsible for transmission of information within the brain and across networks and pathways. It also is the seat of normal brain rhythms that are inhibitory and modulate control of movement.

The thalamus is comprised of multiple nuclei that have specific roles in what information is processed. Depending on the location of an injury, thalamic injury can present as movement disorders, cognitive dysfunction, language difficulty, problems with visual processing, and sleep-wake cycling difficulties. More diffuse

injuries to the thalamocortical pathways (connecting the thalamus to the cortex) have also been found to result in abnormal excitation that may be related to a variety of neuropsychiatric and behavioral disorders. Neuroimaging studies have demonstrated that mild to moderate traumatic brain injury can result in disruption of thalamic resting state networks and that this injury correlates with reduced performance on neurocognitive testing (Han, Chapman, & Krawczyk, 2015). This continues to be an exciting area of research because of the contribution that the thalamic resting state network may have in autism and intellectual disability (Nair et al., 2015).

The Brainstem

In contrast to the cerebral hemispheres, which control voluntary actions, the brainstem controls more reflexive and involuntary activities. It is comprised of three distinct areas (midbrain, pons, and medulla) and connects the cerebral hemispheres to the spinal cord (Figure 8.5). Within it are the cranial nerves that control functions such as vision, hearing, swallowing, and articulation. These cranial nerves also affect facial expression, eye and tongue movement, salivation, and even breathing. In addition to the cranial nerve nuclei, the brainstem is composed of a vast array of fiber tracts relaying messages into and out of the brain. The corticospinal tract provides a passage of neural impulses from the cortex to the spinal cord. Conversely there are tracts that bring sensory information to the cortex via the thalamus. Therefore, any abnormality in this

Figure 8.5. The three regions of the brainstem are shown: midbrain, pons, and medulla. The placement and function of 11 of the 12 cranial nerves are illustrated. (The first cranial nerve [smell] is not shown. It lies in front of the second cranial nerve, below the frontal lobe.) Note that the pyramidal tract runs from the cortex (not shown) into the brainstem. The pyramidal fibers cross over in the medulla. Thus, the right hemisphere controls left-side movement, and the left hemisphere controls right-side movement.

region affects function in distant locations. Children with cerebral palsy may have damage to the brainstem or to pathways that end in the brainstem. This damage might explain the high incidence of excessive salivation, swallowing problems, strabismus, and speech disorders in these children (see Chapter 21).

The Cerebellum

The **cerebellum** (Figure 8.2A and B) resides below the cerebral hemispheres and behind the brainstem. The importance of the cerebellum is increasingly being recognized for its contributions to coordination of voluntary motor activity, cognition, emotion, language, and learning. During the late fetal and early postnatal period, the cerebellum undergoes unparalleled rapid growth and development (Brossard-Racine & Limperopoulos, 2016). It helps coordinate voluntary motor activity by dampening skeletal muscular activity. This enables a smooth transition between activating **agonist** muscles (that work together) and inhibiting their counterpart antagonist muscles. Normal muscle coordination requires that cerebellar functions be integrated with those of the cerebral hemispheres and the basal ganglia. Although voluntary movement can occur without the cerebellum, such movements are **ataxic** (erratic and uncoordinated). An ataxic gait may be seen with cerebellar tumors, progressive neurological disorders (e.g., ataxia telangiectasia), cerebral palsy, certain genetic conditions, or as a side effect of certain medications.

Advanced imaging studies have revealed cortical-cerebellar connectivity during cognitive testing of memory and executive function (Koziol et al., 2014; Nguyen et al., 2017). Imaging using fMRI reveals cerebellar activation during a variety of cognitive tasks including those related to language, visual-spatial abilities, and executive function. Furthermore, resting-state functional connectivity data demonstrate that the cerebellum is part of cognitive networks that include the prefrontal and parietal association cortices (Koziol et al., 2014). The **clinical cerebellar cognitive affective syndrome**, occurring in patients with cerebellar lesions, provides further evidence of cerebellar involvement in cognitive functions. The syndrome causes deficits in spatial processing, working memory, language, and emotional lability (Hoche, Guell, Vangel, Sherman, & Schmahmann, 2017).

A number of theories have been proposed regarding the specific contributions that the cerebellum makes to neural processes, including timing, sequencing, and learning associative relationships among elements (Baumann et al., 2015; Cheron, Marquez-Ruiz, & Dan, 2016; Freeman, 2014). This suggests that the cerebellum is important for extracting relevant information from

the environment and optimizing motor output related to that information. These findings support the theory that the cerebellum is crucial to the formation of internal models, which may apply to both movement and cognitive functions.

The Spinal Cord

The spinal cord transmits motor and sensory messages between the brain and the rest of the body. In addition to permitting voluntary movement, the spinal cord acts to provide protective reflex arcs in both the upper and lower extremities, such as the deep tendon reflex elicited when the knee is tapped. The spinal cord is an elongated, cylindrical mass of nerve tissue that is continuous with the brainstem at its upper end and occupies the upper two thirds of the adult spinal canal within the vertebral column (Figure 8.6). It widens laterally in the neck and the lower back regions. These enlargements correspond to the origins of the nerves of the upper and lower extremities. The nerves of the **brachial plexus** originate at the **cervical** (neck) enlargement of the spinal cord and control arm movement; the nerves of the **lumbosacral plexus** arise from the **lumbar** (lower back) enlargement of the spinal cord and control leg movement. Injury to a newborn's

brachial plexus most commonly occurs during a difficult vaginal delivery, resulting in weakness of the arm (Freeman, Goodyear, & Leith, 2017). Many patients with birth-related brachial plexus injuries recover enough motion and strength and do not need early surgery, but they do greatly benefit from occupational therapy.

The spinal cord is divided into approximately 30 segments—8 cervical, 12 thoracic (chest), 5 lumbar, 5 sacral (pelvic), and a few small coccygeal (tailbone) segments—that correspond to attachments of groups of nerve roots. Individual segments vary in length. They are about twice as long in the midthoracic region as in the cervical or upper lumbar area.

There are no sharp boundaries between segments within the cord itself. Each segment contributes four roots: a **ventral** (front) and **dorsal** (back) root arising from the left half and a similar pair of roots arising from the right half of the cord. Each root is made up of many individual rootlets. The dorsal nerve roots allow sensory input to ascend to the brainstem, whereas the ventral roots deliver motor input from the brainstem to the appropriate muscle.

If the spinal cord is damaged (e.g., due to trauma or a congenital malformation, such as a myelomeningocele), messages to and from the brain are short-circuited below the area of defect. The result is a loss (either partial or complete) of sensation and movement in the affected limbs. The paralysis, which is initially flaccid (hypotonic) but ultimately becomes spastic (hypertonic), may involve the legs (**paraplegia**) or all four extremities (**quadriplegia**) depending on the level of damage.

Figure 8.6. The spinal column. The spinal cord extends from the neck to the lower back. It is protected by the bony vertebrae that form the spinal column. The enlargement to the right shows a section of the cord taken from the upper back region. Note the meninges (the dura, arachnoid, and pia mater) surrounding the cord and the peripheral nerve on its way to a muscle. This nerve contains both motor and sensory components (roots). The spinal cord, like the brain, has both gray and white matter. The gray matter consists of various nerve cells, the most important of which are the anterior horn cells. These are destroyed in polio. The white matter contains nerve fibers wrapped in myelin, which gives the cord its glistening appearance.

Cerebrospinal Fluid and the Hydrodynamic Balance

Cerebrospinal fluid (CSF) is now known to perform many functions. In addition to physically supporting the neural elements and serving to buffer the brain and spinal cord from excessive motion, CSF acts to provide nutritional support as well as remove excessive hormones and neurotransmitters. CSF may also serve as a “relief valve,” adjusting its volume when there is an increase in intracranial pressure.

In adults approximately 600 to 700 milliliters of CSF is produced each day primarily by the **choroid plexus**, a collection of modified ependymal cells lining the ventricles of the brain. This fluid moves throughout the lateral and third ventricles and communicates with the fourth ventricle via the aqueduct of Sylvius (Figure 8.7). At the level of the fourth ventricle, the CSF exits to circulate over the surface of the brain as well as the spinal cord in the subarachnoid space. Absorption of CSF occurs at the **arachnoid granulations** over

Figure 8.7. The ventricular system of the brain. The major parts of the ventricular system are shown (top). The flow of cerebrospinal fluid is shown (bottom). The fluid is produced by the choroid plexus in the roof of the lateral and third ventricles. Its primary route is through the aqueduct of Sylvius, into the fourth ventricle, and then into the spinal column, where it is absorbed. A secondary route is around the surface of the brain. A blockage, most commonly of the aqueduct of Sylvius, leads to hydrocephalus. (Lower illustrations from Milhorat, T.H. [1972]. *Hydrocephalus and the cerebrospinal fluid*. Philadelphia, PA: Lippincott Williams & Wilkins. <http://www.lww.com>. Copyright © 1972, The Williams & Wilkins Co., Baltimore, MD; adapted by permission.)

the superior surface of the brain. These granulations act as one-way valves to allow CSF to move into the blood stream.

Should an imbalance develop between CSF production and absorption, **hydrocephalus** may result (Figure 8.8). This usually congenital condition involves an abnormal accumulation of fluid in the cerebral ventricles, causing skull enlargement in the infant and brain compression. It can be caused by an obstruction of CSF flow within the ventricular system (frequently at the aqueduct of Sylvius) or at the exit of the ventricular system (at the foramina of Luschka and Magendie). This is known as a noncommunicating hydrocephalus. In contrast, a communicating hydrocephalus is caused by a malfunction at the level of the arachnoid granulations. In addition to inadequate absorption, overproduction of CSF can occur, as seen with tumors of the choroid plexus.

When fluid builds up inside the skull of an infant, the **sutures** (the joints connecting the bones of the skull) expand and dissipate the increased pressure at the expense of an increase in head circumference. This may

Figure 8.8. Normal magnetic resonance imaging scan (left) and computed tomography scan showing hydrocephalus (right). In the image to the right, note the rounded appearance of the frontal horns (top) as well as the differentially enlarged occipital horns (bottom). This is known as colpocephaly and is frequently seen in individuals with spina bifida.

present as a bulging **anterior fontanelle** ("soft spot"). The sutures generally close between 9–18 months, so hydrocephalus in a child older than 18 months may quickly lead to headache, vomiting, lethargy, and **focal** (localized) neurological changes. This buildup of fluid can be life-threatening at any age and is considered a medical emergency.

When hydrocephalus occurs, it is necessary to restore the balance between production and absorption of CSF, a treatment often accomplished via a shunting procedure that results in long-term drainage of CSF. The shunt's objective is to bypass the CSF obstruction, whether at the level of the arachnoid granulations or within the ventricular system. This usually involves diverting CSF from the head to another site, preferably the abdomen. The complication rate for this surgery is low, and the long-term outcome is reasonably good. Once in place, however, numerous obstacles remain in maintaining a working shunt and avoiding infection. Many children require shunt revisions as a result of infection or because obstructions develop within the shunt. Managing hydrocephalus, however, has been simplified and often allows for a near-typical lifestyle.

In children with noncommunicating hydrocephalus, either congenital (e.g., aqueductal stenosis) or acquired (e.g., secondary to a tumor), there is a surgical alternative to shunting. This procedure (endoscopic third ventriculostomy) involves perforating the floor of the third ventricle to create a new outflow route for the CSF, thus bypassing the obstruction completely. Endoscopic third ventriculostomy has the benefit of avoiding implants but is not feasible in all individuals with hydrocephalus (Lam, Harris, Rocque, & Ham, 2014).

In addition, there is a small but serious risk of injury to nearby vascular and neural structures (Robertson, Abd-El-Barr, Mukundan, & Gormley, 2017).

THE PERIPHERAL NERVOUS SYSTEM

The peripheral nerves allow neural impulses to move from the CNS (brain and spinal cord) to distant muscles and sensory organs. These nerves can have both motor and sensory fibers that run in opposite directions. Motor, or **efferent**, fibers transmit impulses from the brain to initiate movement, whereas sensory, or **afferent**, fibers carry signals from muscles, skin, and joints back to the brain. Sensory fibers convey information related to the position of a joint or the tone of a muscle following movement. Hyperexcitability of sensory neurons in the child with cerebral palsy contributes to spasticity. There are also a number of hereditary neuropathies that interfere with the peripheral nervous system (Stojkovic, 2016).

The regenerative capacity of the peripheral nervous system differs substantially from that of the CNS. Although the CNS is considered capable of limited regeneration, the peripheral nervous system can be repaired more easily. This ability to promote the regrowth of peripheral nerves is responsible for the success seen in surgical reconstruction for **brachial plexus** palsy sustained during vaginal delivery. The brachial plexus is a network of nerves that conducts signals from the spine to the shoulder, arm, and hand. Brachial plexus palsy is caused by damage to those nerves. Symptoms include a limp or paralyzed arm; lack of muscle control in the arm, hand, or wrist; and a lack of feeling or sensation in the arm or hand. Recovery of partial function is seen in 60%–90% of young children undergoing these procedures (Abid, 2016; Abzug & Kozin, 2010).

The **somatic** nervous system (SNS) is the part of the peripheral nervous system that is associated with the voluntary control of body movements via skeletal muscles and with the sensory reception of touch, hearing, and sight. The SNS consists of efferent nerves responsible for stimulating muscle contraction, including all the neurons connected with skeletal muscles, skin, and sense organs. Complex coordination between the motor and sensory system is necessary to ensure normal muscle tone. An imbalance can lead to either increased or decreased tone. Direct injury to the SNS will affect voluntary as well as reflex activities of the involved muscle and will cause flaccid weakness. This is in contrast to a CNS-presenting motor injury, which will present with increased tone in the form of spasticity.

Involuntary activities of the cardiovascular, digestive, endocrine, urinary, respiratory, and reproductive

systems are controlled by the **autonomic nervous system**. This control begins in the diencephalon and terminates at the end organ (Figure 8.9). In contrast to the graded response of voluntary movements, the autonomic nervous system involves an on/off type of control. The best example of this is the fight-or-flight response. When a person feels threatened, physically or psychologically, several physiological changes take place simultaneously. Digestive system functions are suspended so that blood can be diverted to more important areas for actions involved in fight or flight, such as the brain and heart. Heart rate and blood pressure increase, and the air passages of the lungs expand in size. All of these changes prepare for a quick reaction to an emergency.

Although the autonomic nervous system works involuntarily in maintaining **homeostasis** (metabolic equilibrium of the body), voluntary adjustments come from the cerebral cortex to modulate these effects. The development of bowel and bladder control is the best example of this. In an infant, when the bladder or rectum fills, the outlet muscles release automatically and the infant urinates or defecates with no conscious control. Between the ages of 12 and 18 months, however, the child starts to be able to gain control over these functions. The cerebral cortex begins to send inhibitory signals to reduce the normal autonomic activity. As any parent knows only too well, this coordination requires months (or years) of fine-tuning to master consistent control. Individuals who have sustained damage to either the corticospinal tracts or the spinal cord

Figure 8.9. Autonomic nervous system. These nerves control such involuntary motor activities as breathing, heart rate, and digestion. This figure shows what occurs in fight-or-flight reactions (sympathetic).

are less able to inhibit the autonomic nervous system in this way. This explains the great difficulty that children with cerebral palsy, myelomeningocele, or traumatic brain injury may have in controlling bowel and bladder function.

THE MICROSCOPIC ARCHITECTURE OF THE BRAIN

The Neuron

Neurons are similar to other cells in that they have a cell body consisting of a nucleus and cytoplasm. Unlike other cells, however, they have a long process called an **axon**, which extends from the cell body, and many short jutting processes called **dendrites** (Figure 8.10). The axon carries impulses away from the nerve cell body, sometimes for a distance greater than a meter. Dendrites receive impulses from other neurons and carry them a short distance toward the cell body. The size and shape of dendrites may change with neuronal activity, suggesting that these changes may represent the anatomical basis for memory.

As the brain begins to organize by 5 weeks' gestation (a process that continues into early childhood), neurons develop from neural progenitor cells that first symmetrically proliferate (multiply) during the first 6 weeks of gestation and then shift to asymmetric cell division (Lui, Hansen, & Kriegstein, 2011). Most of the neural progenitor cells that eventually mature into postmitotic neurons are produced in the ventricular zone. They migrate radially to form the six-layered neocortex—with the sixth layer being formed first and the more superficial layers formed later by migrating cells (Lui et al., 2011). Once the neurons have migrated to

Figure 8.10. Illustration of a nerve cell (neuron) showing its component elements. The enlargements show the minute dendritic spines that increase the number of synapses or junctures among nerve cells. Note the diminished size and number of dendritic spines in a child with Down syndrome.

their target region, they grow in size, differentiate, and develop neuronal processes (i.e., axons and dendrites). The major developmental features of this organizational period include 1) the establishment and differentiation of neurons; 2) the attainment of proper alignment, orientation, and layering of cortical neurons; 3) the elaboration of dendrites and axons; 4) the establishment of synaptic contacts; and 5) cell death and selective elimination of neuronal processes and synapses.

As the neurons develop, the growing axons are able to recognize various signaling molecules that are on the surface of other axons and cell bodies. They use these molecules as a means to navigate to their final destination. Based on these signaling cues, the axons move forward (sometimes rapidly), avoid obstacles, and stop when their target is reached. These guidance functions—sensory, motor, and integrative—are contained within the specialized tip of a growing axon, the growth cone (Tamariz & Varela-Echavarria, 2015).

Dendrites and Axons As axons grow toward their respective dendritic targets, the dendrites respond by increasing the number of spines (projections) along their surface (Figure 8.11). The spines increase the surface area of the dendrites, permitting more elaborate communication between the neurons. In fact, increased dendritic outgrowth has been associated with enhanced memory, and deficient development of dendritic arborization has been observed in individuals with cognitive impairment, most notably in Down syndrome (Huttenlocher, 1991).

Figure 8.11. Central nervous system synapse. The enlargement shows the abutting of an axon against a dendritic spine. The space separating the two is the synaptic cleft. Neurotransmitter bundles are released into the cleft from vesicles in the presynaptic membrane. These permit transmission of an impulse across the juncture.

Synapses Proper function of the nervous system requires that two linkages form: 1) the needed communication between an axon from one neuron and the dendrite from a second neuron and 2) the communication between these two neurons once the connection is established. The point of contact between two neurons is called a **synapse** (Figure 8.11).

Synapses can be either chemical or electrical, with distinct characteristics for each type. In electrical synapses, there is a short distance between the two neurons, and there is a communication between the cytoplasm of the cells. Because of this, there is very little delay as an electric current passes from one neuron to the next, and the transmission is usually bidirectional.

In contrast, chemical synapses have a larger gap between the two neurons and no direct communication of the cytoplasm. Small **vesicles** (fluid-filled sacs within cells) containing specific neurotransmitters are released from the axon of one neuron and travel the distance between the cells to reach the receptors for that particular neurotransmitter on the dendrite of the second neuron. The effect on the postsynaptic cell can be either excitatory or inhibitory depending on the neurotransmitter and the cell type. Within a network of cells, electrical and chemical synapses work together to foster synchrony.

During early stages of brain development, there are initially an excess number of connections. This exuberant number of synapses throughout the brain gradually declines beginning during the early postnatal period and continuing throughout childhood and adolescence. This process of elimination of axons and dendrites is known as **synaptic pruning**. The purpose of this process is to remove redundancy and enhance connectivity between pertinent neural networks. During neuronal differentiation, the primitive neurons begin to express their distinctive physical and biochemical features. This process, called **arborization**, is much like the growth of a tree from a sapling. It even involves pruning, such that some new connections (synapses) remain established while others disappear. For example, in the visual cortex, synapses form most rapidly between 2 and 4 months after full-term birth, a critical time for the development of visual function. Maximum synaptic density is attained at 8 months of age, when the elimination of synapses begins. Synaptic strengthening and pruning continue through adolescence and into adulthood.

Glia

Glia account for more than half of the cells in the human brain. These macroglia cells—the oligodendrocytes

and astrocytes—were originally thought to be simply support cells to the neurons. However, they are now known to play a crucial role as regulators of brain development, plasticity, and disease. They arise from neuroepithelial progenitor cells in the embryonic neural tube and prosencephalon. These neural progenitor cells during early embryonic development first give rise to the radial glia that generate neurons (described above). During the later stage of embryonic development, they begin to differentiate into astrocytes and oligodendrocytes.

Astrocytes are crucial for neuronal survival. They take up the nutrients from the vasculature in order to provide metabolic support to neurons. They also play an important role in a phenomena known as neurovascular coupling; they stimulate increased blood flow to the region where neurons are active in order to provide metabolic support for these regions (Mishra et al., 2016). Recent evidence supports the idea that astrocytes are responsible for regulating the flow of cerebral spinal fluid and its homeostasis (Brinker, Stopa, Morrison, & Klinge, 2014). At the synaptic level, they contribute to ionic balance and the removal and recycling of neurotransmitters.

Oligodendrocytes are the other CNS-specific glial cells and are responsible for myelination. Myelination of axons is important because it acts as an insulator, thus facilitating rapid signal transmission with minimal degradation. In the CNS, myelination begins during the third trimester of pregnancy. Oligodendrocyte progenitor cells differentiate and undergo complex morphological changes that result in the extension of their processes so that they can wrap around multiple axons. Due to the lipid content of myelin, its appearance is white. Effective **myelination** is necessary for the development of voluntary gross and fine motor movement and the suppression of **primitive reflexes** (see Chapters 9 and 21). While the majority of myelination occurs during the first 2 years of life, it continues to a lesser extent into early adulthood (Snaidero & Simons, 2014). Deficient myelin formation (hypomyelination) has been found using MRI in a number of conditions, including prematurity, congenital hypothyroidism, and malnutrition (Barkovich & Deon, 2016).

Outside of the CNS, the peripheral nervous system also requires rapid transmission of signals to and from the CNS. The glial cells that are responsible for myelin formation of the PNS are called **Schwann cells**. Unlike oligodendrocytes in the CNS, a single Schwann cell is responsible for wrapping a single axon; in fact, multiple Schwann cells may wrap a single axon. The embryonic origin of the glial cells that develop into Schwann cells are the neural crest cells.

Neurotransmitters

Neurotransmitters are chemicals that are released by one cell to cause an effect on a second cell. They differ from hormones in the scale of their action. While hormones are released into the bloodstream and can affect cells distant from the originating cell, neurotransmitters are released within the synapse and only affect cells that are in very close proximity. For a substance to be considered a neurotransmitter, it has to be synthesized within and released from the presynaptic neuron and has to exert a defined effect on the postsynaptic neuron.

In the case of chemical transmission at a synapse, the first step is the synthesis of the neurotransmitter within the presynaptic neuron. Many of these chemicals share a common precursor. For example, the neurotransmitters dopamine and norepinephrine are both synthesized from the amino acid tyrosine. Each neuron is specialized to use a specific neurotransmitter. After synthesis, the neurotransmitters are packaged and stored in vesicles within the axon to await release. When a **depolarizing current** (an electrical current causing a change in cell membrane voltage) passes through the axon, the vesicles spill their contents into the synapse. The neurotransmitters then travel the distance between the two neurons. The dendrite of the postsynaptic neuron has receptors that are specific for the released neurotransmitter. When the receptors are activated, there can be an excitatory or inhibitory response. The excess neurotransmitters

within the synapse are then removed either by reuptake or by enzymatic breakdown. The function of the CNS can be altered by manipulating any of the steps in chemical transmission. Many commonly used medications for depression and anxiety belong to a group of prescription drugs known as **selective serotonin reuptake inhibitors**. Examples include fluoxetine (Prozac) and sertraline (Zoloft) (see Appendix C). These medications block the reuptake of serotonin after its release in the synaptic cleft, thereby increasing the availability and the duration of serotonin action in specific brain regions. Similarly, atomoxetine (Strattera) is a selective norepinephrine inhibitor and has been found to be effective in treating ADHD. Atomoxetine works differently from stimulant medications that directly stimulate levels of norepinephrine (see Chapter 19). Within the central, peripheral, and autonomic nervous system there are a variety of identified neurotransmitters. Table 8.1 provides a simplified summary of the characteristics of some of the major neurotransmitters.

TECHNIQUES FOR EVALUATING THE CENTRAL NERVOUS SYSTEM

Computed Tomography

High-speed computed tomography (CT) scans, which are produced from multiple thin-cut x-rays, are a routine part of evaluating a child with hydrocephalus,

Table 8.1. Characteristics of some of the major neurotransmitters

Neurotransmitter	Location	Function	Associated disorder
Acetylcholine	Nucleus basalis Neuromuscular junction Autonomic nervous system	Stimulates muscle contraction at the neuromuscular junction	Myasthenia gravis (loss of receptors) Botulism (impaired release)
Dopamine	Substantia nigra	Initiates and controls movement	Parkinson's disease (deficiency) Schizophrenia (excess)
Norepinephrine	Locus ceruleus Sympathetic nervous system	Maintains vigilance and responsiveness	Alzheimer's disease
Serotonin	Raphe nuclei	Involved in the sleep–wake cycle, emotions, food intake, thermoregulation, and sexual behavior	Depression (deficiency)
Histamine	Hypothalamus	Regulates hormones	
GABA	Inhibitory interneurons throughout the brain and spinal cord	Principal inhibitory neurotransmitter	Epilepsy (deficiency)
Glycine	Inhibitory interneurons in the spinal cord	Inhibits antagonist muscles	Nonketotic hyperglycinemia (excess)
Glutamate	Excitatory neurons throughout the brain and spinal cord	Principal excitatory neurotransmitter	Huntington disease (excess) Acute brain injury (excess)

Key: GABA, gamma-aminobutyric acid.

trauma, craniofacial disorders, new-onset seizures, or brain and skull tumors. The CT provides excellent bone definition and allows the physician to discern whether acute brain pathology is present including hemorrhage, edema (swelling), or tumor. Three-dimensional CT scans also can provide sophisticated reconstruction of complex skull-base disorders, while CT angiography offers good resolution of blood vessels and flow abnormalities. CT scans can often be obtained quickly, so they may not require sedation in young children, as opposed to MRI scans, which take longer to acquire, making sedation necessary.

CT can be supplemented with intravenous (IV) contrast, which helps define areas of blood-brain barrier breakdown. The addition of IV contrast is especially helpful in cases of infection or a suspected tumor. Most infections and many (but not all) tumors will appear bright with the addition of contrast, aiding in visualization of these lesions. Conversely, IV contrast typically does not help in certain clinical scenarios such as a closed head injury or hydrocephalus.

While CT is a powerful diagnostic tool, the associated radiation exposure is greater than that from a typical chest x-ray. Not only are children more sensitive to radiation and thus at an increased risk from exposure, but they also will have a longer lifetime than adults for any negative effects from exposure to manifest (Antonucci et al., 2017; Bulas, Goske, Applegate, & Wood, 2009). In addition to the risk to the individual, one must consider the potential population risk of increased cancer rates as use of CT has become more common (Pearce et al., 2012). While CT remains a mainstay in evaluating the child's nervous system in the acute setting (e.g., traumatic brain injury), decreased radiation or alternative methods of imaging, such as MRI, are becoming the mainstay in most diagnostic situations.

Magnetic Resonance Imaging

MRI scanning has surpassed all other imaging modalities for evaluating brain structure. It is particularly useful in investigating developmental abnormalities of the brain, in assessing the causes of epilepsy, in identifying chronic hemorrhage, and in visualizing brain tumors.

Over the last decade, improvements in MRI technology and science have allowed physicians to collect information not only about alterations in structure, but also alterations in function, brain metabolism, and microscopic damage to the brain's gray and white matter. This is done by using special MRI software in the routine MRI scanner. These new sequences have been used clinically as well as part of research studies to learn more about brain networks that underlie

cognition and how different developmental disorders may be similar or different in terms of brain function.

Children with intellectual disability may have a structural cause for the underlying deficit. It may be qualitative or quantitative and therefore can be measured by MRI. Some findings may be nonspecific but nonetheless may be helpful in identifying a physiologic process (e.g., whether it involves the gray matter or white matter), determining the timing of the insult (e.g., an old neonatal stroke versus a recent stroke in a child with sickle cell disease), assessing the potential for reversibility, or following up to see if a condition is static or progressive. Other findings on MRI may be so specific that they help to identify the definitive cause of a child's intellectual disability. An example would be the diagnosis of a major structural brain anomaly such as holoprosencephaly, lissencephaly, or a malformation of the cerebellum (see Chapter 3). Applying the newer modalities of MRI that probe function, microstructure, and metabolism can assess brain injury at its earliest onset as well as provide a basis for following the course of the disease or gauging the effects of interventions.

New discoveries and applications over the past decades include 1) fluid-attenuated inversion recovery imaging, which allows much better analysis of disorders that affect the white matter (see Figure 8.12); 2) fMRI, which enables one to visualize brain activation patterns while a patient performs a cognitive or motor task in the scanner (see Figure 8.13); 3) diffusion weighted imaging and diffusion tensor imaging to look at microscopic damage in white matter; and 4) magnetic resonance spectroscopy (MRS), which enables a noninvasive biochemical examination of the brain (Figure 8.14). A systematic approach based on pattern recognition of brain involvement is particularly useful

Figure 8.12. On routine T2 imaging (left), white matter lesions may be difficult to visualize. However, on the fluid-attenuated inversion recovery imaging (right) sequence the white matter lesions are clearly evident. (Source: Kandel, Schwartz, & Jessell, 2000.)

Figure 8.13. Activation map typical of an fMRI. In this figure, the left motor strip is being activated in the area indicated by the arrows. A task that elicits motor response would be expected to produce such a motor response. In an individual who has motor impairment, this area may show less activation and other areas may activate in a compensatory response.

in the analysis of brain MRI scans in patients with inborn errors of metabolism (see Chapter 16).

Since the mid-2000s, fMRI has emerged as a valuable tool for imaging the time course of activity associated with neurocognitive processes in the brain (Gaillard & Berl, 2012). This technology has wide-ranging applications for both basic research into brain function and for clinical research into the neurophysiology of neurological and psychiatric illness.

fMRI detects minute changes in regional blood flow and metabolism and can be useful in localizing brain regions involved in such activities as reading, speaking, listening, and moving. Differences have been found in individuals with dyslexia versus standard-achievement-level readers (Krafnick, Flowers, Luetje, Napoliello, & Eden, 2014). In epilepsy, fMRI is useful in localizing language and memory function, as well as seizure foci, and it may one day replace more invasive testing of these functions (Gaillard & Berl, 2012).

MRS is a versatile noninvasive technique capable of producing information on a large number of brain metabolites. This technology is readily available and often performed in the same session as conventional MRI. MRS techniques complement conventional and advanced imaging and are proving useful in diagnosing, treating, and predicting progression. To date there are no clear guidelines for the use of MRS in childhood neurological diseases. However, many studies demonstrate that MRS can serve as a useful tool to predict outcome after perinatal brain injury, facilitate the diagnosis of metabolic disorders or mass (tumor) lesions, and provide additive information in the workup of children with epilepsy (Gropman, 2010; Rincon et al., 2016).

The most commonly used spectroscopy in clinical practice is hydrogen (^1H)-MRS. The following neurometabolites can be assessed by MRS: 1) N-acetyl aspartate, a mitochondrial-derived metabolite made in neurons that is a marker of neuronal integrity, neuronal number, and during white matter development

Figure 8.14. ^1H -MRS comparing a normal subject (gray) with a subject with OTC deficiency (black). A peak difference can be seen, specifically, higher Gln in OTC deficiency, lower Cho in OTC deficiency, and ml in OTC deficiency. (Key: ^1H -MRS, hydrogen magnetic resonance spectroscopy; OTC, ornithine transcarbamylase)

is responsible for contributing to myelin lipids; 2) creatine, an energy marker; 3) choline, a cell membrane component; 4) myoinositol, a small sugar that is involved in intracellular signaling, cell volume, and osmoregulation; and 5) lactate, a marker elevated in conditions where energy metabolism is compromised. With special software and more specific acquisition protocols, the neurotransmitters glutamate, glutamine, and GABA can also be measured. Figure 8.14 demonstrates an MRS comparing a normal subject with one of the inborn errors of metabolism, ornithine transcarbamylase.

Single Photon Emission Computer Tomography and Positron Emission Tomography

Like fMRI, single photon emission computer tomography (SPECT) and positron emission tomography (PET) are techniques that demonstrate metabolically active regions in the brain. A radioactive-labeled compound, most commonly glucose, is injected into the bloodstream, and SPECT or PET is then used to assess the compound's selective uptake in various brain regions. Both techniques have been used in the past to diagnose strokes, tumors, and brain injury following head trauma. SPECT and PET have also been employed to evaluate seizure disorders prior to surgery (Kumar & Chugani, 2017). Table 8.2 summarizes the advantages and disadvantages of each of these different imaging techniques. As with CT, there is radiation exposure associated with SPECT and PET scans that must be factored in when weighing the risks and benefits of these diagnostic studies in children.

Electroencephalography

Whereas CT and MRI show the structure of the brain and SPECT, PET, and fMRI show its metabolic activity,

there are additional tests that can be useful in assessing the function of the brain. An electroencephalogram (EEG) utilizes scalp electrodes to measure intracranial electrical activity (see Chapter 22). This is a noninvasive test that detects the summation of neuronal discharges in the superficial layers of the cerebral cortex. In epilepsy, an EEG can show a pattern that is indicative of epileptiform ("seizure-like") activity. Coupled with continuous video monitoring, EEG becomes a powerful tool to match seizure type with the location of the seizure focus in the brain. It can detect seizures that may not be evident clinically and can show the effects of various treatments, both medical and surgical, on seizure activity. EEG is also useful in evaluating mental status changes associated with diffuse neurological dysfunction (as might occur in encephalitis or infection of the brain). The background EEG is important because the frequency (Hertz) of the waveforms is a key characteristic used to define normal or abnormal EEG rhythms. In certain situations, EEG waveforms of a certain frequency for age and/or state of alertness may be viewed as abnormal because they demonstrate irregularities in amplitude or rhythmicity. While the EEG is a useful diagnostic tool, a routine EEG is not completely sensitive or specific. A normal EEG does not rule out the possibility that the patient has seizures or epilepsy. Alternatively, an abnormal EEG does not signify that the patient is having seizures or has epilepsy. Repeated EEG studies as well as careful history taking will increase the yield of diagnosing seizures in patients.

Electromyography and Nerve Conduction Studies

Up to this point, the discussion of techniques for evaluating the nervous system has focused on evaluating the CNS. Although there is limited imaging to assess the peripheral nervous system (e.g., MRI to evaluate the brachial plexus), functional testing is readily

Table 8.2. Advantages and disadvantages of each neuroimaging technique

Imaging technique	Advantages	Disadvantages
Computed tomography (CT)	High resolution of bony anatomy; quick and readily available; usually does not require sedation	Lower resolution of brain structures compared to MRI
Magnetic resonance imaging (MRI)	Extremely high resolution of brain structures; images obtained in multiple planes; no radiation exposure	Takes longer to acquire images compared with CT; often requires sedation
Positron emission tomography (PET)/single photon emission computed tomography (SPECT)	Shows brain function in addition to structure by tracking the uptake of radioactive glucose	Limited availability at many centers
Functional MRI (fMRI)	Shows function by detecting variation in regional blood flow; lends better structural resolution than PET/SPECT	Requires significant patient cooperation; not feasible for individuals who are very young or who have severe intellectual disability

available in the form of **electromyography** (EMG) and **nerve conduction studies** (NCS). These studies involve placement of needle electrodes at various points on the body to test motor and sensory function of the peripheral nerves. EMG and NCS can be used to define traumatic injury or peripheral neuropathy. In addition, these studies can be a helpful aid in surgical cases that involve dissection near either sensory or motor pathways.

SUMMARY

- The nervous system is composed of central and peripheral elements.
- The CNS (the brain and spinal cord) is complex in both its structure and function.
- Various techniques allow better assessment of the brain for diagnosis of a broad range of clinical pathology.
- There are multiple modalities to assess structure and function of the central and peripheral nervous system.
- As the field's understanding of both normal and abnormal neurological function improves, better therapeutic avenues will be forthcoming.

CHAPTER 9

Muscles, Bones, and Nerves

Peter B. Kang

Upon completion of this chapter, the reader will

- Describe how the neuromuscular and musculoskeletal systems function and are integrated
- Recognize the common signs and symptoms of neuromuscular and musculoskeletal disorders
- Learn the utility, appropriate use, and interpretation of standard diagnostic tests for neuromuscular and musculoskeletal disorders
- Identify the most common neuromuscular and musculoskeletal diseases of childhood and their treatments, including recently developed molecular therapies

Together, the neuromuscular and musculoskeletal systems are responsible for the ability to sit, stand, and move; impairments of these systems are major causes of developmental disability in childhood. This chapter provides a general overview of key anatomical structures, identifies the signs and symptoms of neuromuscular and musculoskeletal disorders, describes common disorders of the neuromuscular and musculoskeletal systems, and reviews evaluation and management methods and principles. Importantly, it explains how an integrated health care and school system can improve the lives of children affected by such disorders.

■ ■ ■ CASE STUDY

Praya is a 4-month-old female infant brought to the pediatrician's office for evaluation and treatment for concerns

of floppiness and poor weight gain. She was born full term after an uncomplicated gestation, but her parents report that she feeds poorly and that milk sometimes pools in her mouth. During the examination, she has a weak cry and has trouble lifting her head from the exam table. Her muscle tone seems diminished when she is picked up, both in vertical and prone positions. She has limited antigravity movements of her arms and legs.

Thought Questions:

What should be the overall assessment of this case? Does this infant appear to have a central nervous system or peripheral nervous system disease, and—if so—what features of the clinical presentation would help with the diagnostic evaluation?

OVERVIEW OF THE NEUROMUSCULAR AND MUSCULOSKELETAL SYSTEMS

The neuromuscular system is the neurological network that connects the brain and spinal cord to the musculoskeletal system. Its major components are 1) the **anterior horn cells** (lower motor neurons) in the spinal cord, 2) the peripheral nerves in the extremities, 3) the neuromuscular junction, which joins the nerves and muscles, and 4) the skeletal muscles (Figure 9.1). The

musculoskeletal system consists of the skeletal muscles, tendons, bones, joints, and ligaments.

In order for a muscle to produce voluntary movement across a joint, an electrical signal originates in the cortex of the brain (within an upper motor neuron) and then passes through the spinal cord to an anterior horn cell; there, an axon extends down a peripheral nerve until it ends at a neuromuscular junction (Figure 9.1). The electrical impulse triggers the release of the neurotransmitter acetylcholine, which jumps across the synapse, or gap, at this junction. The acetylcholine binds

Figure 9.1. The neuromuscular system. The central components of the nervous system include the brain and spinal cord. Descending corticospinal pathways carry signals from the brain through the spinal cord to motor neurons in the anterior horns of the spinal cord. The motor neurons are generally regarded as being the first segment of the peripheral nervous system. Signals are transmitted from the motor neurons down the peripheral nerves, then across the neuromuscular junction to skeletal muscle. These signals initiate muscle contraction, leading to movement of the musculoskeletal system. Sensory signals are transmitted from the sensory nerves to the spinal cord, and then to the brain, which continuously integrates this information to monitor the state of the environment and the neuromuscular and musculoskeletal systems.

to receptors in the muscle fiber; and these receptors generate a new electrical signal that propagates through the muscle fiber and stimulates muscle contraction.

The **sarcomere** is the basic contractile unit in the muscle fiber; it is composed of a number of proteins that bind to each other in a dynamic manner. To help organize, modulate, and coordinate motor activities, signals are sent to the brain through the sensory system, providing information about the body's position in space.

The main function of skeletal muscle is to contract by shortening, thereby moving limbs, with joints used as fulcrums. **Agonist** muscles reinforce each other's movements, while **antagonist** muscles oppose one another. For example, when you flex your arm at the elbow, the biceps contracts, as does the brachialis; the triceps, however, relax. If all these muscles contracted simultaneously, your arm would be held stiffly in an **isometric contraction** (i.e., muscular contraction against resistance in which the length of the muscle remains the same). Therefore, to move your arm, the brain sends signals that generate contraction of some muscles and relaxation of others in that arm.

The bones of the skeleton form the body's internal scaffolding. They range in size from the auditory ossicles (inner ear bones) that measure less than a half inch each at the long axis to the femur (thigh bone), which is roughly 18 inches long in adults. As growth takes place and the bone is subject to different forces, the bone responds by changing its shape, a process referred to as remodeling. These changes usually increase the tensile strength and stability of the bone, making it less susceptible to fracture. On average, a given portion of a child's bone turns over approximately once a year. In an adult, the reshaping continues even though growth has stopped. The average bone segment of an adult turns over approximately every 7 years.

SYMPTOMS AND SIGNS OF NEUROMUSCULAR AND MUSCULOSKELETAL DISORDERS

Neuromuscular and musculoskeletal disorders classically present with motor impairments as cardinal symptoms, with weakness and other findings such as gait abnormalities identified on examination. It is important to note that in some cases, respiratory, cardiac, and sensory symptoms may be initial or dominant components of the clinical presentation. Spine abnormalities such as scoliosis, kyphosis, and lordosis, along with contractures, may in some cases be **idiopathic** (cause unknown), especially scoliosis, but in other cases they may provide a diagnostic clue to the presence of these disorders.

Respiratory and Cardiac Issues

In most cases, respiratory and cardiac issues do not arise from neuromuscular or musculoskeletal disorders. However, they constitute frequent complications of these disorders, especially respiratory issues. In addition, in rare instances, they may constitute early manifestations of such conditions. Examples include late-onset **Pompe disease** (a genetic lysosomal storage disorder), in which respiratory distress may be an early symptom, and Becker muscular dystrophy, in which cardiomyopathy is sometimes the first sign of disease. Some neuromuscular disorders affect the respiratory muscles, resulting in an abnormal sleep pattern or **sleep apnea** (brief periods of respiratory arrest). These children may suffer from daytime somnolence and often appear fatigued or easily distractible at school.

Muscle Bulk, Tone, and Strength

Pseudohypertrophy (apparent muscle enlargement due to overgrowth of connective tissue), especially of the calves and in conjunction with weakness, may be a sign of **Duchenne muscular dystrophy (DMD)** and Becker muscular dystrophy; less frequently it accompanies other muscular dystrophies. In contrast, muscle atrophy is found in neuropathies such as **Charcot-Marie-Tooth disease (CMT)** but may also be seen in some myopathies and muscular dystrophies.

It is important to differentiate between tone abnormalities and strength abnormalities. Tone is the muscle's passive ability to respond to stretch, whereas strength represents the force that the muscle exerts actively. Children can have **hypertonia** (high tone and an overreactive response to a normal stimulus) or **hypotonia** (low tone, with a lesser response to a stimulus). Many neuromuscular or musculoskeletal disorders are linked to disturbances in tone. Hypertonia and spasticity are seen primarily in central nervous system (CNS) disorders that affect the upper motor neuron or its axons in the brain and spine, whereas hypotonia can be seen not only in lesions of the CNS (upper motor neuron), but also in peripheral nervous system (lower motor neuron) involvement. In infants, preserved strength in the setting of hypotonia is usually associated with a central nervous system process, whereas weakness in conjunction with hypotonia is usually associated with a peripheral nervous system process.

Muscle weakness can be **proximal** (involving muscles or body segments closer to the center of the body) or **distal** (involving muscles or body segments farther from the center of the body). Proximal muscle weakness affects the shoulder and hip girdle muscles (often

seen in **myopathies**, which are primary disorders of muscle). Children with weak shoulder and hip girdle muscles have difficulty rising from a floor or chair, reaching objects on a high shelf, climbing jungle gyms, and/or doing push-ups. Testing the ability of the child to grasp and manipulate objects demonstrates selective control, a skill necessary to operate hand controls. Children with distal muscle weakness may thus have trouble holding a pen or pencil, finishing long writing activities on time, and/or using scissors. Proximal or distal lower extremity weakness often causes gait abnormalities (see the following sections).

Sensation

Sensory symptoms such as numbness, **paresthesias** (abnormal skin sensations, such as burning, prickling, itching, and tingling) and pain may result from disorders of the peripheral sensory nerves (e.g., peripheral neuropathies) or from CNS disorders. Sensory nerve fibers tell the brain where the body is in space, so affected children may have a clumsy gait or feel unsteady in the dark, requiring visual input for balance.

Scoliosis, Kyphosis, and Lordosis

Scoliosis is a **lateral** (sideways) curvature of the spinal column, **kyphosis** is an excessive **anterior** (forward) curvature of the spine, and **lordosis** is an excessive **posterior** (backward) curvature. Isolated scoliosis in an otherwise healthy child or adolescent is usually not associated with a neuromuscular or musculoskeletal condition. Idiopathic scoliosis occurs frequently during the adolescent growth spurt, especially in young women. However, scoliosis, kyphosis, lordosis, or a combination of these may be complications of numerous neuromuscular and musculoskeletal disorders. The appearance of these vertebral abnormalities in a younger child or of one of them in conjunction with other concerning findings should prompt careful evaluation.

Because spinal curves are best managed before they become severe, the spine of a child at greater risk (e.g., a child with meningocele or muscular dystrophy) should be examined regularly. Early clues suggesting scoliosis are unequal heights of the shoulders or a slanting of the waist. Also, as the ribs attach to the thoracic (chest level) spine, they may follow the curve of the vertebrae, causing a rib rise or “rib hump” when the child bends forward. School screening examinations for scoliosis are designed to look for these physical findings in order to detect scoliosis as early as possible.

Contractures and Gait Abnormalities

When a neuromuscular or musculoskeletal disorder prevents full range of motion around a joint for a prolonged period of time, a joint **contracture** (shortening of the tendons around a joint) can develop, resulting in a fixed loss of joint motion. In an ankle joint contracture, the Achilles tendon shortens and the child walks on his or her toes. Toe-walking, limping, walking with a wide-based gait, and other gait abnormalities should prompt a medical evaluation.

In an ambulatory child, observing the gait pattern is a valuable part of the physical examination. During normal gait, the head and trunk should be level, with minimal sway from side to side. The child should be able to maintain balance while standing on one leg and swinging the opposite leg through. The leg that is swinging should clear the ground, and the foot should not drag.

Strong pelvic muscles are needed for a child to rise from a seated position and to climb stairs. Children with hip girdle weakness often need to pull on a handrail to walk up steps or to push off with their hands in order to rise from a chair. To get up from the floor, such children often use a Gowers maneuver: First, they turn to face the floor; then they use their hands on the floor to support part of their weight as they straighten their knees; and, finally, they push their hands on their thighs to achieve an erect posture.

Distal muscle weakness (often seen in neuropathies) affects the hands and feet; children may trip and fall frequently because they cannot lift their feet or toes when walking. They also may not be able to walk on their heels and may “slap” their feet while walking (a condition called *foot drop*). Orthotic devices may stabilize distal leg weakness and lessen the frequency and severity of falls.

Joint Abnormalities

Joint abnormalities can be identified with range-of-motion testing. Range of motion is a passive assessment, meaning the patient should be relaxed while the examiner moves the extremities. The upper extremities should be examined for range of motion of the shoulders, elbows, and hands. The examiner should be able to lift the child’s arms above the head. The elbows should straighten fully, often even a few degrees beyond full extension (known as hyperextension). All fingers should be able to be straightened and brought out of the palm.

The hip exam, like the spine exam, should be performed often, as early treatment of hip problems leads to the best outcomes. The examiner should be able to

abduct (spread apart) the hips easily and symmetrically. Loss of hip abduction may indicate a hip dislocation or **subluxation** (partial dislocation). Another means of assessing whether the hip is dislocated is to look for discrepancies in knee heights with the hips and knees flexed and the ankles together, while the patient is **supine** (lying on their back).

The knee must be straight for standing, but it must flex to 90 degrees for comfortable sitting and flex even farther for easy stair climbing. Contractures of the hamstrings can limit knee movement and impair the ability to stand.

The ankle should be examined for **plantarflexion** (downward motion of the foot) and **dorsiflexion** (upward movement of the foot). The ability to dorsiflex beyond a neutral position is important for both walking and sitting and should be tested with the knee both extended and flexed. A child should be able to maintain the feet in a **plantargrade** (flat on the floor) position while walking and maintain as much flexibility in the feet as possible. Heel cord contractures, which may lead to balance problems and toe-walking, are commonly seen in a range of neuromuscular disorders, including muscular dystrophies.

LABORATORY TESTING AND RADIOGRAPHY

There is an ever-expanding array of diagnostic options available for neuromuscular and musculoskeletal disorders, most prominently genetic testing and advanced imaging modalities such as ultrasound and extremity MRI studies. However, it is important to remember the ongoing importance of more traditional test modalities, such as basic serum muscle enzyme measurements, electrophysiology, and muscle and nerve biopsies.

Serum Testing

Measurements of muscle enzyme levels in **serum** (the protein-rich liquid that separates out when blood coagulates) are useful as initial screening laboratory tests in the evaluation of potential neuromuscular disorders, especially due to their low costs. The most well-known of these is the creatine phosphokinase (CPK), also known as the creatine kinase level. Aldolase is also useful as an adjunctive muscle enzyme marker. Significant elevations in muscle enzyme levels suggest the presence of a muscle disease. Mild to moderate elevations may be difficult to interpret, as they may be normal variants, signs of muscle disease, or sometimes signs of a neurogenic disease such as spinal muscular atrophy.

Genetic Testing

Genetic testing for mutations (see Chapter 1) has been a boon to diagnosing inherited diseases, including neuromuscular and musculoskeletal disorders, and it can spare an increasing number of patients from invasive and painful diagnostic procedures such as electromyography and biopsies. However, genetic test results are not always definitive and must be interpreted with care. Close coordination with a geneticist or another physician who is experienced in diagnosing and treating the disease in question will increase the likelihood of accurate application to clinical practice. Thus, traditional diagnostic tests for neuromuscular disease remain relevant and useful for many of these patients for the foreseeable future.

Electrophysiology

Nerve conduction studies and **electromyography** (EMG), a recording of electric potentials found in muscle fibers, are useful in diagnosing a variety of neuromuscular disorders, including anterior horn cell disease, neuropathies, neuromuscular junction disorders, and some myopathies. Advances in genetic testing and immunohistochemistry of biopsy specimens have changed referral patterns for pediatric patients with suspected neuromuscular disorders (Karakis, Liew, Darras, Jones, & Kang, 2014). In particular, Duchenne and Becker muscular dystrophies are now primarily diagnosed with genetic testing and these patients are rarely referred to the EMG laboratory. Spinal muscular atrophy is usually diagnosed with genetic testing as well, although in cases in which the diagnosis must be confirmed rapidly, EMG is still important prior to genetic confirmation. EMG continues to play an important role in the initial evaluation of Charcot-Marie-Tooth disease, as many children present with subtle signs that raise the possibility of this diagnosis but end up not having a neuropathy (Karakis, Gregas, Darras, Kang, & Jones, 2013). EMG is technically demanding and should be performed only by an electromyographer experienced in performing these studies in children. This is important both for diagnostic accuracy and for the comfort of the child, as the procedure involves electrical stimulations during the nerve conduction studies, followed by needle examination of the muscle. EMG remains useful for a range of diagnostic neuromuscular questions in children (Karakis et al., 2014).

Biopsy

Muscle, nerve, and skin biopsies have traditionally been essential to the diagnosis of many neuromuscular

and musculoskeletal disorders. Genetic testing, however, has changed the profile of patients who are referred for these tests; patients with Duchenne and Becker muscular dystrophies rarely need muscle biopsies, as they can usually be diagnosed by identification of mutations from blood samples. Genetic testing has also begun to supplant muscle biopsy in suspected cases of limb-girdle muscular dystrophy, although a higher proportion of these patients will need biopsies at some point during their evaluations. When biopsies are needed, advances in genetics and biochemistry have enhanced the sophistication of their interpretation, as immunohistochemistry of biopsy sections can detect protein deficiencies that may indicate a specific genetic defect.

Radiography

Abnormal musculoskeletal exam findings can be illuminated by plain x-rays of the involved areas, which can help detect movement limitations caused by bony deformity. X-rays are helpful in detecting the shapes of bones but are a poor gauge of the quality of bone because bone loss will not be apparent until at least one third of the bone is gone. Bone density is best measured by a bone density scan.

Ultrasonography and magnetic resonance imaging (MRI) have only recently been applied to the evaluation of possible muscle disorders, but certain myopathies show distinct patterns of muscle involvement that may be detected by such methods (Wattjes, Kley, & Fischer, 2010). These tests have the potential to spare some children from undergoing invasive diagnostic procedures such as muscle biopsy, or to assist in the selection of a muscle for biopsy that may have an optimal diagnostic yield.

DISORDERS OF THE NEUROMUSCULAR SYSTEM

Within the traditional anatomical categories of neuromuscular disorders (anterior horn cell disease, neuropathy, disorders of the neuromuscular junction, and muscle disease), knowledge of various genetic and immune etiologies has expanded knowledge to a remarkable degree in the past several decades.

Anterior Horn Cells: Spinal Muscular Atrophy

The nerve cells (neurons) in the spinal column that control movement are called anterior horn cells. In the past, the most well-known disease associated with

damage to the anterior horn cell was paralytic poliomyelitis. Thanks to the polio vaccine, this viral illness is no longer endemic in the United States. Currently, the most common disorder affecting the anterior horn cell in children is **spinal muscular atrophy** (SMA; Darras & Kang, 2007).

SMA is characterized by degeneration of alpha-motor neurons in the brainstem and spinal cord. There is a subsequent involvement of motor nerves, leading to progressive weakness that is nearly always predominantly proximal and symmetrical, with diffuse weakness in more severe cases and at later stages of disease. Intelligence is preserved (von Gontard et al., 2002). Most cases are associated with homozygous deletions in the *SMN1* gene, making this an autosomal recessive disorder (Lefebvre et al., 1995; Melki et al., 1994). SMA was historically the most common inherited cause of death in infancy, with an estimated incidence of 10 to 16.7 per 100,000 live births (Merlini, Stagni, Marri, & Granata, 1992; Pearn, 1973; Pearn, 1978); these estimates have more recently been adjusted to 8.5 to 10.3 per 100,000 live births (Arkblad, Tulinius, Kroksmark, Henricsson, & Darin, 2009; Jedrzejowska et al., 2010; Lally et al., 2017; Prior et al., 2010; Sugarman et al., 2012). SMA has traditionally been divided into three clinical variants based primarily on the milestones attained: SMA I, SMA II, and SMA III.

SMA I Children with SMA I (previously known as Werdnig-Hoffman disease) have onset typically before 6 months of age and are never able to sit or walk. Infants with SMA I develop diffuse hypotonia and weakness with **areflexia** (lack of deep tendon reflexes). Swallowing and breathing difficulties are serious, life-threatening complications that may occur at any time. Without interventions, affected children rarely survive beyond 2 years of age and often die much earlier. This prognosis, however, has changed dramatically with recent therapeutic developments. Placement of gastrostomy feeding tubes and respiratory interventions, including both noninvasive and invasive options, can extend these children's life expectancies, sometimes for years. If a gastrostomy tube is to be placed, it should be done as early as possible. Lung interventions may include pulmonary hygiene (used to clear mucus and secretions from the airways), noninvasive pressure support ventilation (delivery of mechanical ventilation without the need for artificial airway), and tracheostomy with full mechanical ventilation. Families and physicians should decide collaboratively on a treatment plan based on their ethical judgment about the quality of life they feel is best.

SMA II In SMA II, patients sit at some point during childhood, but never walk. Onset is usually between 6 and 18 months. Infants and toddlers with SMA II typically present with hypotonia, areflexia, and delayed motor milestones. They are also susceptible to difficulties swallowing and breathing, but these complications tend to occur later and progress more slowly than in SMA I. Nutritional and respiratory therapies are similar to those used in SMA I. Scoliosis is a frequent and disabling complication in these children, for which spine surgery is often helpful. Depending on the severity of the individual case and the level of intervention, life expectancy has traditionally ranged from late childhood through early adulthood. More recent advances in ventilatory approaches to these patients, and novel molecular therapies have dramatically improved this prognosis.

SMA III Patients with SMA III are able to sit and walk, and they usually have onset of motor difficulties after 18 months of age but before adulthood. Children with SMA III often present with gait difficulties, proximal weakness, and areflexia, sometimes severe enough to cause delayed motor milestones. The weakness is almost always symmetrical, though some exceptions have been described (Kang, Krishnamoorthy, Jones, Shapiro, & Darras, 2006). Hypotonia, while present, is not as prominent a feature. Difficulties swallowing and breathing are rare, and life expectancy is usually not affected.

Therapy Until recently, therapy for SMA was primarily supportive. However, a novel antisense oligonucleotide drug (nusinersen) has been developed that has shown efficacy and safety in symptomatic infants with SMA I and II and was approved by the U.S. Food and Drug Administration (FDA) in 2016 (Finkel et al., 2016; Finkel et al., 2017; Mercuri et al., 2018a) (see Box 9.1). The therapy must be administered **intrathecally** (into the spinal canal) and at this time requires ongoing dosing indefinitely. Further studies are ongoing regarding the use of gene therapy approaches as well (Mendell et al., 2017).

Disorders of the Peripheral Nerves: Charcot-Marie-Tooth Disease (CMT)

Neuropathy and *peripheral neuropathy* are general terms that imply that some damage has occurred to the nerve. Neuropathies can be motor, sensory, or sensorimotor (a combination of the two). The term *mononeuropathy* implies that only a single nerve is damaged, whereas *polyneuropathy* refers to a generalized process that affects all or most nerves, albeit with varying degrees of severity. The acute autoimmune neuropathy, Guillain-Barré syndrome, usually does not lead to significant prolonged disability, with the exception of some cases that involve prominent axonal loss; it will not be discussed in detail here.

BOX 9.1 EVIDENCE-BASED PRACTICE

Effect of Treatment with Nusinersen on Outcome in Spinal Muscular Atrophy

Spinal muscular atrophy is an autosomal recessive neuromuscular disorder that is caused by an insufficient level of survival motor neuron (SMN) protein. Nusinersen is an antisense oligonucleotide drug that modifies pre-messenger RNA splicing of the *SMN2* gene and thus promotes increased production of full-length SMN protein, correcting the defect. The authors conducted a randomized, double-blind, sham-controlled, phase 3 efficacy and safety trial of nusinersen in infants with spinal muscular atrophy (SMA I and II). The primary treatment goals were improved motor-milestones and prolonged survival of this usually rapidly fatal disease. In the study a significantly higher percentage of infants in the nusinersen group than in the control group had improved motor milestones (37 of 73 infants [51%] vs. 0 of 37 [0%]). Furthermore, the likelihood of survival was higher in the nusinersen group than in the control (untreated) group. Infants identified and treated earlier were more likely than those with a longer duration disease to benefit from nusinersen. In summary, among infants with spinal muscular atrophy, those who received nusinersen were more likely to be alive and have improvements in motor function than those in the control group. Early treatment may be necessary to maximize the benefit of the drug.

From Finkel, R. S., Mercuri, E., Darras, B. T., Connolly, A. M., Kuntz, N. L., Kirschner, J., . . . Endear Study Group. (2017). Nusinersen versus sham control in infantile-onset spinal muscular atrophy. *New England Journal of Medicine*, 377(18), 1723–1732; reprinted by permission.

CMT disease is the most common inherited polyneuropathy; in an epidemiologic study from Norway it was found to affect 1 in 1,214 individuals (Braathen, 2012). An alternative term for this disorder, *hereditary motor and sensory neuropathy*, is also used. CMT is classified based on the inheritance pattern (autosomal dominant or recessive) and physiology (demyelinating or axonal). *Demyelination* refers to a disease process in which the myelin insulation surrounding nerve axons is stripped off, whereas axonal loss refers to a process in which the axons themselves degenerate.

The major categories of polyneuropathies are CMT1 (dominant, demyelinating), CMT2 (dominant, axonal), CMTX (X-linked, axonal and/or demyelinating), and CMT4 (recessive, axonal and/or demyelinating). Déjerine-Sottas disease was previously known as CMT3 and is a rare, early-onset form of CMT that may be associated with more significant long-term motor disabilities than the classic phenotype of CMT. There is genetic and phenotypic overlap with congenital hypomyelinating neuropathy. The most common form of CMT is CMT1A, which is caused by a duplication in the *PMP22* gene (Lupski et al., 1991). Hereditary neuropathy with liability to pressure palsies (HNPP) is a related disorder in which patients are susceptible to compression neuropathies after minor trauma. HNPP is typically caused by a deletion of the *PMP22* gene rather than a duplication.

Onset of CMT depends on the specific type and may occur at birth or not until adulthood, but many cases are diagnosed in the first 2 decades of life. Patients with CMT typically present with weakness and wasting of the foot and lower leg muscles, which may result in foot drop and a high-steppage gait with frequent tripping and falling. Foot deformities, such as **pes cavus** (high arches) and hammertoes (a condition in which the ends of the toes curl downward), result from weakness of the intrinsic foot muscles (Laura et al., 2018). Some children can present with **pes planus**

(flat feet) and need arch supports. The degeneration of myelin, axons, or both results in muscle weakness and atrophy in the extremities, and the degeneration of sensory nerves results in a reduced ability to feel heat, cold, and pain. Because of the muscle weakness, contractures develop over time, especially at the heel cords, and sometimes curvature of the spine occurs (Shy, 2004).

In general, CMT is slowly progressive, and people with most forms of CMT have a normal life expectancy. There is currently no cure, but physical therapy, occupational therapy, braces and other orthopedic devices, and orthopedic surgery (see Box 9.2) can help individuals with CMT finish school, work, and live functional lives despite the disabling symptoms of the disease (Bertorini, Narayanaswami, & Rashed, 2004; McDonald, 2001; Shy, 2004). Vitamin C therapy has been investigated for the treatment of CMT, but clinical trials in adults (Micallef et al., 2009; Verhamme et al., 2009) and children (Burns et al., 2009) showed no clear benefit.

Diseases of the Neuromuscular Junction: Myasthenia Gravis

The peripheral nerves end at the neuromuscular junction. For a nerve impulse to cross the synapse separating the nerve and muscle, the chemical neurotransmitter acetylcholine must be released from the nerve terminal, cross the space between the nerve and muscle, bind to its receptor on the muscle membrane (much like a key fitting into a keyhole), and generate the muscle membrane impulse that will transmit the signal to the contractile structures within the muscle cell. Impairment of any of the mechanisms that allow a nerve impulse to transmit signals to stimulate muscle movement can result in a myasthenic disorder (from *myo* meaning muscle and *asthenia* meaning fatigability). In rare instances, myasthenic syndromes are genetic

BOX 9.2 INTERDISCIPLINARY CARE

Orthopedic Surgery

Orthopedic surgery, or orthopedics, is the branch of surgery concerned with conditions involving the musculoskeletal system. In the pediatrics age group orthopedic surgeons use both surgical and nonsurgical means to treat musculoskeletal disorders and other developmental disabilities as well as acute injuries such as broken bones. Pediatric orthopedic surgeons train as residents and fellows for at least 6 years following medical school. For children with developmental disabilities, they may perform surgery to correct hip dislocation, spinal curvatures, and/or spasticity. They also work as part of a rehabilitative team (see Chapter 32) to design orthoptical supports, wheelchair assistance, and physical and occupational therapy.

in origin (called congenital myasthenic syndrome), but they are most often acquired as autoimmune disorders. In children and adolescents, acquired autoimmune myasthenia is typically referred to as juvenile myasthenia gravis. The most common symptoms are **diplopia** (double vision), **ptosis** (drooping eyelid), **dysphagia** (difficulty swallowing), **dysarthria** (changes in voice quality), and extremity weakness. These symptoms result from cranial nerve involvement, which is almost always present. The symptoms tend to worsen with activity and toward the end of the day. In the most severe cases, breathing and swallowing may be impaired (Chiang, Darras, & Kang, 2009).

Treatment of juvenile myasthenia gravis generally targets improving neuromuscular transmission and increasing muscle strength while suppressing the production of abnormal antibodies. Pyridostigmine is a drug that is a common first-line therapy. It is an acetylcholinesterase inhibitor, which means that it prevents the neurotransmitter acetylcholine from being metabolized at the neuromuscular junction, raising its effective levels. At high doses, pyridostigmine can cause cholinergic side effects (including excessive secretions and sometimes worsening of myasthenia symptoms), but in general it is well tolerated. Its main drawback is that it is a relatively weak therapy, and often patients will need immunomodulatory therapy as well.

There are three standard immunomodulatory therapies available for myasthenia gravis: plasmapheresis, intravenous immunoglobulin, and steroids (Liew et al., 2014). Plasmapheresis requires central venous access (a surgically placed central line into a large central vein) in younger children and others with small-caliber peripheral veins. In older children and adolescents with large-caliber veins, the treatments can be performed through a peripheral vein (standard intravenous therapy). Intravenous immunoglobulin has also been used in some cases. Steroid therapy may be the most traditional approach, but it is associated with significant side effects when used on a long-term basis, especially in children and adolescents. When a child needs additional therapy beyond the traditional immunomodulatory therapies, steroid-sparing immunomodulatory agents may be used. Due to the significant side effect profile of chronic corticosteroid use, steroid-sparing agents are likely to be used before steroids in the future.

Thymectomy is a surgical procedure that removes the thymus, a gland in the chest that plays a key role in regulating immune responses. This procedure appears to induce partial or complete remission in some cases of juvenile myasthenia gravis (Kogut, Bufo, Rothenberg, & Lobe, 2000; Tracy, McRae, & Millichap, 2009).

Disorders of Muscle: Muscular Dystrophies and Myopathies

The two major categories of inherited muscle disease in childhood are muscular dystrophies and congenital myopathies. Muscular dystrophies are characterized by the progressive destruction of muscle tissue, whereas congenital myopathies typically involve either the abnormal accumulation of certain proteins or other developmental abnormalities in the muscle fibers. These findings can be observed on microscopic examination of skeletal muscle tissue obtained at biopsy.

Muscular dystrophies tend to be progressive, whereas the clinical course in congenital myopathies varies. There is a vast array of muscular dystrophies, including limb-girdle muscular dystrophies, congenital muscular dystrophies, facioscapulohumeral muscular dystrophy, and Emery-Dreifuss muscular dystrophy. Genetic etiologies have been defined for each of these categories of disease.

Duchenne Muscular Dystrophy DMD is the most common form of muscular dystrophy in childhood. It is a progressive skeletal muscle disorder caused by mutations in the X-linked DMD gene, resulting in the absence of dystrophin, a major muscle protein (Hoffman, Brown, & Kunkel, 1987; Monaco et al., 1986). The incidence of Duchenne muscular dystrophy is approximately 1 in 3,300 male births (Jeppesen, Green, Steffensen, & Rahbek, 2003). This disorder is associated with a high spontaneous mutation rate (Van Essen, Busch, te Meerman, & ten Kate, 1992), so a significant number of boys with Duchenne muscular dystrophy have no family history of the disease.

The disease manifests in early childhood, although abnormal muscle CPK levels and microscopic signs of muscle damage may be observed at birth. Delayed walking and frequent falls are characteristic initial symptoms. Boys with Duchenne muscular dystrophy often walk on their tiptoes. Manifestations of proximal hip girdle muscle weakness become apparent by 3–5 years of age when the child starts having difficulties climbing in the playground, getting up from the floor, climbing stairs, and running. Weakness in the quadriceps and gluteus maximus muscles makes it difficult for the child to rise from the floor to a standing position, and affected boys use the Gowers maneuver (described earlier) to compensate. Weakness in the gluteus medius muscles leads to a waddling gait. **Pseudohypertrophy** (enlargement that is due primarily to fibrosis and fatty infiltration of muscle, rather than a true increase in muscle fiber diameter or numbers) of various muscles occurs, most commonly at the calves (Figure 9.2).

Figure 9.2. Pseudohypertrophy of the calf muscles in a 5-year-old boy with Duchenne muscular dystrophy, characterized by a deletion in exon 45 in *DMD*, the dystrophin gene. (Courtesy of Peter B. Kang, M.D.)

Accelerated deterioration in strength and balance often results from intercurrent disease or surgically induced immobilization. If tendon releases are performed, mobilization in a walking splint or cast is needed as soon as possible to prevent a decrease in muscle strength from disuse. When ambulation is no longer possible, typically by the ages of 10–12 years, contractures in the lower extremities become more pronounced and may involve the shoulders. Daily physical therapy and occupational therapy services at school and daily stretching exercises at home are imperative.

Corticosteroid treatment of Duchenne muscular dystrophy has become a standard component of clinical care, although the optimal age for initiation of this therapy remains controversial (Birnkrant et al., 2018b). Oral prednisone (a steroid medication) stabilizes or improves strength and, in many cases, prolongs the ambulatory phase of the disease by 1–3 years (Griggs et al., 1993). The synthetic steroid deflazacort was approved by the FDA in 2017 due to evidence suggesting that it may have a milder side effect profile compared with prednisone, especially with respect to weight gain (Griggs et al., 2016). One exception to the finding of a lower side effect profile is the formation of asymptomatic cataracts, which tends to be more

common with deflazacort (Biggar, Gingras, Fehlings, Harris, & Steele, 2001; Campbell & Jacob, 2003; Moxley et al., 2005). At this time, the differences in side effect profiles are relatively modest so that either corticosteroid is a viable option (Griggs et al., 2016). Dietary supplements have generally not been found to improve outcome (Escolar et al., 2005).

Kyphoscoliosis (abnormal curvature of the vertebral column in two planes, a combination of kyphosis and scoliosis) can develop at any time but typically accelerates after ambulation is lost. This complication not only causes pain and postural problems, but also exacerbates pulmonary issues due to loss of effective lung volume. Baseline spine x-ray images should be obtained for comparison with future studies to monitor the development of scoliosis. Both manual and power wheelchairs are useful. When the kyphoscoliosis is severe enough, usually at 30 to 50 degrees of curvature, spinal fusion surgery with rod placement may be warranted to help preserve lung function and improve posture (Brook, Kennedy, Stern, Sutherland, & Foster, 1996). The optimal time for surgical intervention is while lung and cardiac functioning is satisfactory (Finder et al., 2004).

Cardiac and respiratory abnormalities are almost universal in the later stages of the disease, and one or the other of these complications constitutes the immediate cause of death in most cases. Cardiac manifestations include cardiomyopathy and cardiac arrhythmias. The progression of cardiomyopathy (inflammation of the heart muscle impairing its function) may be slowed by the use of certain drugs. Progressive respiratory failure occurs from a combination of decreased lung capacity and function. Noninvasive ventilatory support, in combination with interventions to promote appropriate secretion clearance and coughing, is now commonly recommended to counteract this decline.

Lower-than-average IQ scores have been reported in individuals with Duchenne muscular dystrophy, although results have not been consistent and many children have typical cognition (Felisari et al., 2000). Certain cognitive areas such as verbal memory, digit span, and auditory comprehension are more affected than others (Hinton, De Vivo, Nereo, Goldstein, & Stern, 2000). Deletions localized in a specific part of the dystrophin gene are preferentially associated with cognitive impairment (Giliberto, Ferreiro, Dalamon, & Szijan, 2004). The incidence of neurobehavioral issues, ranging from attention-deficit/hyperactivity disorder to autism spectrum disorder, seem to be increased as well in boys with Duchenne muscular dystrophy (Hendriksen & Vles, 2008; Wu, Kuban, Allred, Shapiro, & Darras, 2005).

The life expectancy for patients with Duchenne muscular dystrophy without significant interventions

was previously less than 2 decades. The supportive and medical therapies, including spinal fusion surgery, steroids, cardiac medications, and noninvasive ventilatory support, have together helped lengthen the life expectancy in many cases to the fourth decade and in some cases to the fifth decade. Treatment by a multidisciplinary neuromuscular team is critical to implementing such a care plan.

The only treatment that has had an effect on the primary muscle weakness in Duchenne muscular dystrophy has been corticosteroids, as previously noted. In 2016, however, an antisense oligonucleotide therapy (eteplirsen), given by intravenous injection weekly, was approved by the FDA to restore the reading frame of the dystrophin gene in certain boys with Duchenne muscular dystrophy. This approach, referred to as exon skipping, appears to have the potential to partially restore the reading frame of the gene in patients with mutations amenable to skipping of exon 51 in dystrophin, representing about 13% of affected boys (Mendell et al., 2016). More treatments that take advantage of exon skipping are expected to follow in the years to come.

Congenital Myopathies Congenital myopathies usually present in infancy with marked hypotonia and weakness, feeding difficulties, and respiratory insufficiency. Within each type of congenital myopathy, there is a spectrum of severity, and later onset variants have been identified for several subtypes due to advances in genetic diagnosis (Dubowitz & Fardeau, 1995; Ryan et al., 2003). In contrast to muscular dystrophies, congenital myopathies are more likely to be associated with cranial nerve involvement (facial weakness, eye movement abnormalities, or both) and early respiratory complications.

The classic congenital myopathies include centronuclear myopathy (including X-linked myotubular myopathy), nemaline myopathy, central core disease, and congenital fiber type disproportion (Riggs, Bodensteiner, & Schochet, 2003). These diseases are listed in order of decreasing overall severity, although there is overlap among these subtypes.

Causative mutations in various genes that encode structural muscle proteins, often localizing to the sarcomere, have been linked with each type of congenital myopathy. Mutations in the *MTM1* gene cause myotubular myopathy (Laporte et al., 1996), and centronuclear myopathy has been associated with several genes to date: *DNM2* (Bitoun et al., 2005), *BIN1* (Nicot et al., 2007), and *RYR1* (Wilmshurst et al., 2010). Nemaline myopathy has been associated with mutations in an ever-increasing number of genes, including *ACTA1* (Nowak et al., 1999), *CFL2* (Agrawal et al., 2007), *NEB*

(Pelin et al., 1999), *TNNT1* (Johnston et al., 2000), *TPM2* (Donner et al., 2002), and *TPM3* (Laing et al., 1995). Central core disease and isolated malignant hyperthermia have been associated with mutations in the *RYR1* gene (Quane et al., 1993; Zhang et al., 1993). The clinical spectrum of *RYR1* myopathies continues to expand.

Caring for a child with a congenital myopathy will depend on specific complications. Respiratory interventions include invasive (i.e., tracheostomy and mechanical ventilation) and noninvasive supports depending on the individual case. A range of orthotic devices and orthopedic procedures may be helpful at various stages of the disease. Nutritional support may also be needed. No pharmacological treatment currently exists for any form of the disorders, though recent research has shown promising results for gene therapy in animal models of myotubular myopathy (Daniele et al., 2018; Elverman et al., 2017; Tasfaout et al., 2018), and a human clinical trial is thus underway. These children generally have typical cognitive development, so education should be provided at the appropriate age and grade level. However, some children may have difficulty speaking due to facial and tongue weakness and sometimes due to a tracheostomy, so an augmentative/alternative communication evaluation is essential (see Chapter 36). Rehabilitation focuses on improving daily living skills (see Chapter 32).

DISORDERS OF THE MUSCULOSKELETAL SYSTEM

Musculoskeletal disorders may involve abnormalities of just one limb or joint or the entire skeleton. This section discusses the different types of musculoskeletal disorders, providing an example of each. These include joint disorders, such as arthrogryposis; skeletal dysplasias, such as achondroplasia; and connective tissue disorders, such as osteogenesis imperfecta.

Joint Disorders: Arthrogryposis

The term **arthrogryposis** refers to congenital joint contractures. Arthrogryposis multiplex congenita is a syndrome in which arthrogryposis is present in at least two major joints, with an incidence estimated to range from 1 in 3,000 to 1 in 12,000 live births (Darin, Kimber, Kroksmark, & Tulinius, 2002). The final common pathway for the development of the characteristic contractures is significant prolonged fetal immobility (Gordon, 1998). More than 150 distinct causes of arthrogryposis multiplex congenita have been identified (Hall, 1997). The etiologies can be divided into endogenous (having an internal cause or origin) and exogenous (having an

external cause or origin) categories. Endogenous causes are often genetic in nature and include multiorgan system genetic syndromes, connective tissue diseases, and central and peripheral nervous system disorders. Exogenous causes are typically maternal and include structural uterine problems, placental insufficiency, maternal myasthenia gravis, and maternal multiple sclerosis (Livingstone & Sack, 1984). When a neuromuscular cause of arthrogryposis multiplex congenita is suspected, electrophysiological testing and muscle biopsy are complementary and should both be pursued when possible (Kang et al., 2003).

Although spinal deformity at birth is uncommon for infants with arthrogryposis, 35% of patients will develop scoliosis or lordosis by adulthood (Nouraei, Sawatzky, MacGillivray, & Hall, 2017). Most curves are resistant to bracing. Physical therapy and occupational therapy, however, are helpful in maintaining joint motion and maximizing functional development. In cases of arthrogryposis associated with other congenital anomalies, the child may have additional medical problems that must be addressed.

Long-term orthopedic management is directed at maximizing function. Because arthrogryposis can be caused by many disorders, there is no single management plan. The common goals are independent ambulation or wheelchair mobility, self-care, and the ability to be employed and live independently. The initial treatment of any contracture involves gentle stretching and range-of-motion exercises. Once the joint is in a proper position, a lightweight splint may help prevent recurrence. If a joint's range of motion is not functional, casting or surgical soft-tissue release followed by casting may improve it. The limitations of surgical interventions should be kept in mind in this patient population (Lahoti & Bell, 2005).

Skeletal Dysplasias: Achondroplasia

The skeletal dysplasias are a large, genetically diverse group of conditions characterized by abnormalities in the development, growth, and maintenance of the skeleton. Many of these disorders result in disproportionate short stature (Savarirayan & Rimoin, 2002). There are approximately 175 different skeletal dysplasias (OMIM, 2011; Orioli, Castilla, & Barbosa-Neto, 1986; Stoll, Dott, Roth, & Alembik, 1989).

Achondroplasia is the most common form of short stature associated with disproportionately shortened limbs. The incidence has been estimated to be 3.6 to 6.0 in every 100,000 live births in the United States (Waller et al., 2008). It has been found to result from a point mutation in the gene coding for fibroblast growth

factor receptor 3 (Matsui et al., 1998). The condition is inherited as an autosomal dominant trait, and most individuals have the same genetic mutation, so the condition's physical manifestations tend to be similar across individuals (Bellus et al., 1995). It is important to monitor affected children for potentially serious complications such as hydrocephalus, craniocervical junction compression (a decrease in the space between the lower brainstem and cervical cord that can lead to spinal cord compression), upper airway obstruction, and kyphosis (Trotter & Hall, 2005).

Thoracolumbar kyphosis (curvature of the mid-lower spine in the front to back plane) is present to some degree in most infants with achondroplasia as a result of their enlarged heads, hypotonia, and ligamentous laxity (double jointedness). The kyphosis typically improves spontaneously once the child begins to walk, but 10%–15% of children require bracing or surgical correction of the curvature (Ain & Browne, 2004; Ain & Shirley, 2004). Careful monitoring is essential, and support for the back, particularly in the very young child, may be helpful.

The major impairments of the extremities include short limbs, limited elbow and hip extension, and knee and leg deformities that can impede ambulation. **Genu verum** (bowed legs) occurs in 40% of individuals with achondroplasia, but only 25% will experience a clinically significant deformity that requires surgical correction (Beals & Stanley, 2005). Significant advances have been made in surgical limb-lengthening procedures, but it still takes about 3 years to achieve the desired lengthening. Growth hormone therapy has achieved only limited success in people with achondroplasia (Hagenas & Hertel, 2003), and impacts on final adult heights are modest (Harada et al., 2017), so it is not regarded as standard of care.

Connective Tissue Disorders: Osteogenesis Imperfecta

Connective tissue disorders are caused by the mechanical failure of collagen (the main structural protein found in skin and other connective tissues), which results in joint hypermobility. Examples of connective tissue disorders include Ehlers-Danlos syndrome and Marfan syndrome.

Osteogenesis imperfecta (OI) is caused by a failure of formation of type I collagen, the scaffolding on which bone mineral is laid down. Bone deformities and frequent fractures are typical complications of this disease. Blue **sclera** (the part of the eye that is normally white) is a classic physical finding in this disease, but a true blue color is typically only seen in type I, whereas

bluish-gray sclera or normal sclera are more typical in other subtypes. Poor dentition is seen in more severe cases. Traditionally, the clinical diagnosis of OI has been supported by a skin biopsy to test for the underlying genetic defect (Minch & Kruse, 1998), but genetic testing of blood leukocytes is now the standard diagnostic approach (Van Dijk & Silience, 2014). OI has been estimated to have a prevalence of 9.5 in 100,000 births (Lindahl et al., 2015). Causative mutations are most commonly found in *COL1A1* (on chromosome 17) and *COL1A2* (on chromosome 7) (Lindahl et al., 2015), though numerous other associated genes have been identified.

Orthopedic care has been the mainstay in managing OI and involves measures to prevent fractures, treat acute fractures, and correct bony deformities. People with OI are particularly susceptible to disuse osteoporosis (bone weakness); therefore, promoting mobility in both daily life and after an injury is essential. Placing rods inside the bones for support at the time of a fracture or in conjunction with **osteotomies** (surgical cuts through the bone to correct deformities) can improve the bone alignment, shorten rehabilitation time, and help prevent future fractures. Scoliosis occurs in 39%–80% of individuals with OI (Wallace, Kruse, & Shah, 2017). Because thoracic curves can decrease lung capacity (Widmann et al., 1999), orthopedic consultation is recommended for monitoring curve progression, with spine fusion surgery performed if necessary (Engelbert, Pruijs, Beemer, & Helders, 1998).

The bone fragility seen in OI is due to disturbed organization of bone tissue, decreased bone mass, and altered bone geometry. Children with OI do not form as much bone compared with unaffected children, and children with moderate to severe OI form essentially the same amount of bone as they resorb. This imbalance informs the rationale for treating affected children with bisphosphonates (e.g., alendronate, typically used to treat osteoporosis in postmenopausal women), and these are now commonly prescribed for this disorder. Bisphosphonate therapy has been shown to increase bone mineral density, but it is not certain yet whether these treatments reduce the incidence of fractures and other clinical complications, and it is not clear what regimen of bisphosphonate therapy is optimal, including the question of the relative merits of oral versus intravenous administration (Dwan, Phillipi, Steiner, & Basel, 2016).

MANAGEMENT PRINCIPLES

Recommended standards of care have been published for Duchenne muscular dystrophy (Birnkranz et al.,

2018a, Birnkranz et al., 2018b, Birnkranz et al., 2018c; Bushby et al., 2010a; Bushby et al., 2010b) and spinal muscular atrophy (Finkel et al., 2018; Mercuri et al., 2018b), and these standards provide greater detail regarding the care of such disorders. While they are by no means the last word on the subject, they summarize what is currently known about caring for children with these conditions and what gaps in knowledge persist.

General management principles for the care of children with neuromuscular and musculoskeletal disorders involve medical care, rehabilitation management, preventing contractures promoting bone health, and providing educational services; these approaches are described below.

Medical Care

The autoimmune neuromuscular disorders, including chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) and myasthenia gravis, typically respond to immunomodulatory therapies including plasmapheresis, intravenous immunoglobulin, and steroids. Guillain-Barré syndrome (closely related to CIDP) responds to immunomodulatory therapies and intravenous immunoglobulin.

Two important precautions apply to patients with primary muscle diseases:

1. **Rhabdomyolysis** (breakdown of muscle tissue) and **myoglobinuria** (the resulting spillage of myoglobin, a heme pigment, into the urine) may occur in isolation or as part of certain muscle diseases (Mathews et al., 2011). These complications occur especially in the context of strenuous exercise, dehydration, or both. Whenever this reaction occurs, the individual should be taken to the nearest emergency department immediately, as the myoglobinuria aspect of the reaction has the potential to cause permanent kidney damage. Intravenous fluids will avert renal injury in most cases.
2. **Malignant hyperthermia** (a life-threatening elevation of body temperature associated with the administration of an anesthetic agent) can occur in patients with *RYR1* mutations (MacLennan et al., 1990; McCarthy et al., 1990) or in the setting of muscle diseases, including muscular dystrophies and congenital myopathies such as *RYR1*-associated central core disease (Quane et al., 1993; Zhang et al., 1993).

Medical therapies for inherited neuromuscular disorders are often limited, but there are important medications for certain disorders. Albuterol (an asthma medication) appeared to increase patients' strength in

two studies involving patients with SMA II (Kinali et al., 2002; Pane et al., 2008), and some clinicians now prescribe this for certain SMA patients. Its efficacy, however, has not been proven in a randomized controlled trial. Steroids have been shown to improve the motor outcome in Duchenne muscular dystrophy, as discussed earlier. Also, specific subtypes of congenital myasthenic syndrome respond to various medications. It is important to note that new molecular therapies are being developed, and a handful have been recently approved for spinal muscular atrophy and Duchenne muscular dystrophy, as described earlier.

It is important for children with neuromuscular disease to have routine immunizations as recommended by the American Academy of Pediatrics (2010), especially when there is a high risk of pulmonary complications. They should also receive the pneumococcal and annual influenza (flu) vaccine. Certain immunizations may need to be deferred for some patients, such as those with active or recent episodes of Guillain-Barré syndrome and patients with active cases of CIDP. Parents of such patients should discuss the advisability of having certain vaccinations with the child's physicians.

Children with myopathies and muscular dystrophies are at increased risk for sleep apnea. Symptoms may be noticeable during daytime and often involve fatigue, falling asleep during class, or morning headaches. A **polysomnogram** (sleep study) with continuous carbon dioxide monitoring is the best way to assess the need for ventilatory support. Provision of noninvasive nocturnal ventilation can significantly increase the quality of life and lengthen life expectancy (Baydur et al., 2000).

Rehabilitation Management

Physical therapy and rehabilitation play an important role in maximizing functional status and tone, and they may even slow the progression of some diseases, although this effect is subtle and difficult to prove. Some evidence suggests that such interventions may have a beneficial impact on outcomes for these diseases (Cup et al., 2007), but it is clear that further data are needed to draw definitive conclusions (Dunaway et al., 2016).

In muscular dystrophies there is a consensus that high-resistance exercises, especially those involving eccentric contractions (i.e., weight lifting and abdominal crunches), are damaging to the muscle cell membrane and should be avoided (Ansved, 2003). However, the impact of a sedentary life is equally negative (McDonald, 2002). Therefore, active, nonresistive

exercises are encouraged, such as swimming (with the proper safeguards). An active lifestyle will also prevent excessive weight gain, especially if the child is receiving steroids. Daily walks help maintain strength and slow contracture formation (see Chapter 32).

Both the nature and quantity of activity should be modified so that fatigue does not remain after a night's sleep. Wheelchair games can be played when ambulation is lost. Children with neuromuscular disorders who are confined to bed because of the disease, injury, or surgery require physical therapy, including range-of-motion exercises, with prompt progression to more active exercise, including walking when possible. In the event of leg fractures, walking casts should be used as soon as possible (Siegel, 1977), and every effort should be made to limit the amount of time the child spends in a cast.

For those children who develop difficulty with activities of daily living, occupational therapy evaluation at school is essential to assess self-feeding, self-care, torso positioning within the classroom, and writing. A keyboard should be provided to complete school tasks, and an assistive technology evaluation should be performed. A voice recorder is useful for taking notes, or a note-taker can be appointed. Some students may require a classroom aide in order to participate fully in the academic environment and safely navigate the school building, and this should be built into their individualized education program (see Chapter 33).

Preventing Contractures

Stretching exercises, nighttime splinting, or both should be recommended as soon as tightness of the heel cords is noticed in order to prevent contractures (Hyde et al., 2000). A standing board tilted at an appropriate angle may be used for limited periods during the day to help stretch the Achilles tendon in children who do not ambulate. If stretching and **orthoses** (bracing) are not effective, surgical release of tight heel cords may be beneficial (Goertzen, Baltzer, & Voit, 1995). Temporary bracing after tendon surgery is necessary for optimal results. Further details on orthoses may be found in Chapter 32.

Promoting Bone Health

In children with neuromuscular and musculoskeletal disorders, a fracture can occur with little or no trauma (e.g., from gentle range-of-motion exercises during physical therapy). Such fractures are called pathologic fractures and may result from bone fragility (especially in osteogenesis imperfecta), as a secondary effect of a

medication (e.g., steroids or antiepileptic drugs), or as weakness from disuse (Sambrook & Jones, 1995). Children may manifest pathological fractures as swelling and increased warmth of the fractured extremity. Weight-bearing activities are important for maintaining bone density as bones have internal receptors that recognize weight-bearing activity and send signals to make bones stronger in response. Similarly, it is essential that these children be given diets rich in calcium and vitamin D, with supplementation of vitamin D recommended in many cases depending on the specific disease and the stage of illness.

Educational Services

Children with acute neuromuscular disorders including myasthenia gravis, inflammatory myopathies, and inflammatory neuropathies may require prolonged admissions to the hospital, which can entail extended absences from school. Some children require home-bound instruction during convalescence. Once the child returns to school, supportive measures such as physical therapy and occupational therapy may be very helpful (Table 9.1). Children with fluctuating disorders

Table 9.1. School accommodations for children with neuromuscular and musculoskeletal disorders

Physical and occupational therapy
Stretching
Range-of-motion exercises
Muscle cramp massage
Safety training (on stairs and playground)
Hallway safety
Accommodating activities of daily living to changing physical needs (e.g., toileting, lunchtime/cafeeteria safety)
Adapted or modified physical education and sports for individuals with disabilities
Consultation for body positioning, seating, and gross- and fine-motor function
Assistive technology
Specialized accommodations
Provision of an additional set of textbooks to avoid having to transport books from one classroom to another
Access to an elevator
Consideration of students' physical needs when designing class schedule
Preferential seating in the classroom
Consideration of students' physical needs when developing a school emergency evacuation plan
Consideration of students' needs when planning field trips and school events

such as myasthenia gravis may require access to elevators, modified physical education programs, additional rest periods during the day, or a shortened school day. Children with chronic disorders such as congenital and hereditary progressive myopathies, as well as chronic polyneuropathies, may require specialized rehabilitation care.

Steroids are used in neuromuscular diseases such as Duchenne muscular dystrophy, chronic inflammatory demyelinating polyradiculoneuropathy, and myasthenia gravis. Two side effects, behavior problems and weight gain, may occur shortly after starting the medication and may persist. Changes in behavior related to the chronic treatment could impact school performance and interpersonal relationships. Steroids can cause depression, hyperactivity, and behavioral changes, including, in rare instances, psychosis. Sometimes adjusting the dose can improve these symptoms, but in other cases the side effects are severe enough that the medication needs to be discontinued.

A child receiving steroids also tends to have increased appetite and weight gain, as well as slowing of linear growth and bone demineralization. Unwanted weight gain can be especially detrimental in children with a neuromuscular disease, including those with muscular dystrophies. The increased body weight burdens the already weak muscles, and this can obscure the benefits of steroid treatment. This problem can sometimes be avoided or mitigated, however, if the child follows a healthy diet. Children on steroids should bring lunch to school whenever possible in order to follow their diet, and they should avoid snacks between meals.

SUMMARY

- The neuromuscular and musculoskeletal systems support the physical structure of the body and help carry out essential movements.
- Diseases affecting these systems have a significant impact on a child's functional capacity and independence.
- Classic signs and symptoms of these diseases may in some cases be straightforward, but in other cases they may be subtle or involve other organ systems and thus be difficult to recognize.
- Genetic advances over the past several decades have facilitated detailed descriptions of genetic subtypes of numerous disorders.
- The child's care team should include family members; primary care physicians; and medical

specialists such as child neurologists, orthopaedic surgeons, therapists, and rehabilitative specialists.

- The goals of therapy are to gain or retain function, conserve energy, prolong life expectancy when possible, and improve quality of life.
- Therapy may involve a combination of medical and nonmedical approaches, including medications; bracing; physical therapy; occupational therapy; seating systems; adaptive equipment; and, when necessary, surgery.
- Historically, cures have been elusive, but this has begun to change as highly sophisticated disease-modifying therapies are beginning to win approval from the FDA for some of these disorders.
- These disorders are under active investigation, with the goal of developing new treatment approaches, including the repair of genetic material, more effective medications, and improved surgical techniques.

CHAPTER 10

Nutrition

Lina Diaz-Calderon, Virginia Gebus, and Laurie S. Conklin

Upon completion of this chapter, the reader will

- Understand nutritional requirements and their assessment in children
- Identify how developmental disabilities modify nutritional requirements
- Recognize the fundamental role of nutrition in the growth and development of children
- Be aware of how nutritional interventions are included in a child's care plan
- Understand the importance of working with a multidisciplinary team to tailor a specific approach to nutrition support based on the child and family's needs

Food selection and preparation are major cultural characteristics of all societies, and within the context of home and family, providing and preparing meals for children expresses parental love and concern. Nutrition is the study of foods, their nutrients, and other components of the diet that affect biological processes and health (Brown, 2014). Human requirements for protein, fats, carbohydrates, vitamins, and minerals vary with age, activity level, medical diagnosis, genetic heritage, and physiological state (Institute of Medicine, 2005). For many children, a regular diet prepared by the family provides all of the nutrients, minerals, and vitamins needed for typical growth and development. In children with developmental disabilities, however, a typical diet may present challenges. For instance, as a result of motor impairments a child with cerebral palsy (CP) may have difficulty ingesting sufficient food (see Chapter 21). A child with autism spectrum

disorder (ASD) may have food selectivity that results in nutritional deficiencies (see Chapter 18). Conversely, a child with Prader-Willi syndrome often engages in **hyperphagia** (pathological overeating), and a child with **meningomyelocele** may become obese through inactivity.

The impact of nutrition is greatest during infancy and childhood, when the body is actively growing; optimizing growth and nutrition in this period can improve cognitive outcomes (Harding, Cormack, Alexander, Alsweiler, & Bloomfield, 2017). For children with developmental disabilities, however, the need for medical nutritional therapy (MNT) may be lifelong. MNT is defined as the manipulation of nutrients and dietary components to affect a disease or condition (American Dietetic Association, 2010). This therapy also takes into account the psychosocial environment in which the child lives. This chapter focuses on the nutritional

needs of children with developmental disabilities and emphasizes MNT as part of a comprehensive care plan.

■ ■ ■ CASE STUDY

Abraham is a 12-year-old boy, born at 34 weeks' gestational age, who has spastic quadriplegia and chronic lung disease. He has been hospitalized several times for pneumonia. His weight plots at a z-score of -2.6 and height at a z-score of -2.7, but his BMI percentile is normal. Over time, his z-scores have become further from the normal range. On a cerebral palsy (CP) growth chart, stratified for age, degree of motor involvement, and tube feeding status, his weight-for-age plots less than the 20th percentile in the "zone of concern," where increased morbidity and mortality may result because of impaired nutritional status (Rempel, 2015). Abraham's parents report an intake of over 2,000 calories daily, but when observed eating a meal, Abraham has significant losses due to oropharyngeal incoordination, poor bolus formation, and inadequate control of bolus propulsion. He is noted to have gastroesophageal reflux and coughing while feeding, and meals take well over 45 minutes to complete. Abraham had a modified barium swallow study with a speech therapist, which demonstrated laryngeal penetration with thin and thickened liquids, but not with pureed consistency. A meeting to allow shared decision making was held, which included the family, physician, and registered dietician. At this meeting Abraham's risk of aspiration and effects of malnutrition on his health were discussed (Adams, Elias, & Council on Children with Disabilities, 2014), as well as the benefits of MNT. As a result, a nasogastric tube was placed for administration of supplemental feedings overnight and boluses during the day (Kuperminc et al., 2013). Abraham continues to consume and enjoy pureed foods in smaller amounts. Water was added to his feeding regimen in order to meet his full fluid needs daily. The management of constipation with this increase in fluids and the addition of a stool softener has improved his tolerance of feedings. Abraham continues to see his dietician for regular guidance regarding his trajectory of weight gain and adjustments to his feeding regimen to suit the family's daily schedule.

Thought Questions:

Who are the team members that contribute to nutritional evaluation and support for children with disabilities, and what roles do they play? What are some of the most common nutritional issues for children with developmental disabilities? What are some ways to provide proper nutrition to a child who is unable to ingest food and drink in a typical way?

TYPICAL GROWTH DURING CHILDHOOD

Nutritional requirements for infants and children are determined by what is needed to produce optimal growth and development. The average full-term infant weighs 3.4 kilograms (about 7.5 pounds) at birth and gains 20 to 30 grams (about 1 ounce) each day for several months. By 4–6 months of age, the infant's birth weight has doubled, and by 12 months, it has tripled (National Center for Health Statistics, 2000, 2008a; Weintraub, 2011). As the child becomes more active, weight gain slows to about 2.5 kilograms per year until approximately 9–10 years of age, when the adolescent growth spurt begins. Length advances at a slower pace than weight, increasing by 50% during the first year of life (from an average of 50 centimeters or about 19.5 inches at birth), doubling by 4 years of age, and tripling by 13 years of age. Age-based reference ranges for height velocity in U.S. children have been described (Kelly et al., 2014). Another measure of growth, increase in head circumference, parallels brain growth. Head circumference increases by approximately 1 centimeter per month during the first year of life. Brain weight doubles by 1 year of age and quadruples by 3 years of age (Dekaban, 1978; National Center for Health Statistics, 2000, 2008a).

In addition to the basic measures of growth (i.e., weight, length, and head circumference), a number of useful growth indices have been developed to provide a more nuanced and clinically relevant way of measuring a child's nutritional status. Among these, the formula used most often is the **body mass index** (BMI), a measure of the relationship between weight and stature (length) for children older than 2 years of age that was developed by the Centers for Disease Control and Prevention (CDC; National Center for Health Statistics, 2010; see Table 10.1). By placing weight into the context of a child's overall size and body habitus, the BMI can be a useful screening tool to assess whether a child is overweight or underweight (NCD Risk Factor Collaboration, 2017). The measurements of weight and stature can be plotted on the World Health Organization (WHO) growth charts for infants and children from 0 to 2 years of age (https://www.cdc.gov/growthcharts/who_charts.htm), the CDC growth charts for children and adolescents from 2 to 20 years of age (https://www.cdc.gov/growthcharts/clinical_charts.htm), or the CP growth charts that include children up to 20 years of age and separates them using the Gross Motor Function Class System. The CP growth chart allows children to be plotted based on a population with similar functional disabilities. When using these charts, weight between the 20th and 95th percentile is acceptable (Brooks, Day, Shavelle, & Strauss, 2011). However, some children may

Table 10.1. Growth parameters and nutrition assessment^a

Growth parameter	Utility in nutrition assessment
Weight for age z-score	Key parameter for monitoring short- and long-term changes in nutritional status
Length for age z-score	Key measure of linear growth and assessment of long-term nutritional status
Head circumference for age (inches or centimeters)	Key proxy for brain growth
Weight-to-height proportionality z-score	Provides a rough estimate of nutritional status by relating weight to stature; birth to 24 months of age (WHO growth charts)
Body mass index z-score (BMI = weight in pounds × 703 / height in inches × height in inches)	Provides an estimate of body fat relative to weight and height; > 2 years of age (CDC growth charts)
Rate of weight and length accretion (change in weight or length over a given time interval)	Precise method of tracking patterns and rates of growth
Body fat indices	Direct measures of body fat using reliable, specialized equipment and techniques

^aMay apply specialty (disease-specific) growth charts for growth assessment.

have an altered body composition that can skew these measurements and interpretations; for instance, a child with CP may have microcephaly or contractures. In these situations, triceps skinfold thickness and mid-upper arm circumference are used as a proxy for body composition (i.e., lean and fat mass; Addo & Himes, 2010; Addo, Himes, & Zemel, 2017; Mramba et al., 2017). A triceps skinfold measurement is a screen for depleted fat stores. A mid-arm circumference assesses a child's muscle mass, bone, and fat reserves and can be measured in a reproducible way (Rempel, 2015). While these measurements require specialized equipment and techniques that are not as widely available, they do offer an even more accurate way of assessing this critical aspect of a child's nutritional status.

NUTRITIONAL GUIDELINES

Research-based nutrition guidelines published by the National Academies of Sciences estimate daily intake of specific vitamins and minerals based on age and gender (Institute of Medicine, 1997, 2001, 2005, 2010). Energy and protein intake recommendations were updated in 2006 (Institute of Medicine of the National Academies, 2006) and have been incorporated into the nutrients included in food labels. They are also reflected in the standard growth charts commonly used by health care professionals (National Centers for Health Statistics, 2000; WHO Multicentre Growth Reference Study Group, 2006). The concept of a “balanced diet” derives from these standard nutritional guidelines and is based on the notion that typical children will require specific amounts and proportions of certain nutrients. Although these guidelines are a good starting point for determining the nutritional requirements for children

with disabilities, adjustments are often required. In some cases, an apparently “unbalanced” diet is appropriate for a child with a specific condition. An all-liquid diet or a diet of only a few different foods may be recommended for a child with limited oral-motor skills. For a child with a special metabolic condition for example, it may be critically important that certain elements of the diet be reduced, eliminated, or enhanced to avoid the buildup of toxic metabolites. Table 10.2 provides other examples of how specific dietary components and calorie content can be manipulated to address the special needs of specific medical conditions and disabilities (Isaacs & Zand, 2007).

NUTRITIONAL ISSUES IN CHILDREN WITH DEVELOPMENTAL DISABILITIES

Children with developmental disabilities have many of the same nutrition issues as typically developing children. These include being overweight or underweight, refusing to eat or drink a variety of foods and beverages, and fighting for control with parents at mealtimes. However, children with neurological impairments are at risk for multiple nutrition-related problems including poor linear growth, micronutrient deficiencies, and low bone mineral density (Romano et al., 2017). They are also prone to more serious and varied problems that are especially related to impaired oral motor skills (e.g., swallowing incoordination among children with cerebral palsy), medical problems (e.g., chronic gastroesophageal reflux among children with hypotonia or a history of prematurity; see Box 10.1), delayed gastric emptying, and food refusal (e.g., dislike of certain food textures among children with ASD; Bandini et al., 2010; Romano et al., 2017). As a result, common nutritional

Table 10.2. Dietary adjustments for specific medical conditions and disabilities

Dietary element	Condition	Specific adjustment required
Fats	Smith-Lemli-Opitz syndrome	Cholesterol (purified form) increased
	Long-chain fatty acid oxidation disorders	Fat decreased, greater than 75% of nutrition from fat-free foods
	Uncontrollable seizures	Ketogenic diet, fat increased
Proteins	Phenylketonuria, maple syrup urine disease	Natural protein decreased by more than 80%, addition of protein substitutes, vitamins, and minerals
Carbohydrates	Glycogen storage disease type 1	Specific types of sugar (e.g., sucrose, fructose, galactose, lactose) decreased
	Galactosemia, lactose intolerance	Specific types of sugar (e.g., galactose, lactose) decreased
	Hereditary fructose intolerance	Specific types of sugar (e.g., fructose) decreased
Vitamins and minerals	Vitamin B ₁₂ disorders	Vitamin B12 increased, often protein content decreased
	Iron-deficiency anemia	Foods rich in iron increased or supplemental iron added
	Rickets	Foods rich in calcium and vitamin D increased or supplements added
Energy (calorie)	Obesity and overweight	Calories decreased 10%–30% (fats, proteins, carbohydrates), activity level increased
	Hypotonia in Down syndrome or Prader-Willi syndrome (if obese)	Calories decreased 30%–40% (fats, proteins, carbohydrates)

advice for typically developing children may not be appropriate for children with developmental disabilities (see Table 10.3). Instead, diets may need to be targeted to specific conditions and/or developmental disabilities, as illustrated in Table 10.2.

Undernutrition

Pediatric malnutrition (undernutrition) is defined as an imbalance between nutrient requirement and intake resulting in cumulative deficits of energy, protein, or micronutrients that may negatively affect growth, development, or other relevant outcomes (Mehta et al., 2013). Recognizing undernutrition and malnutrition in children with disabilities may be difficult because nutrient needs and activity levels may be higher or lower than typical, as noted above (Penagini et al., 2015). For example, short stature is usually not a sign of limited nutrition in children with Turner syndrome (Cohen et al., 2008). Thin appearance is common in spastic quadriplegia (a severe form of cerebral palsy; Motil, 2010; see Chapter 21). However, concern about the adequacy of energy intake is more common in children with disabilities than in typically developing children. Needs for increased energy and protein are commonly observed in children with such conditions as prematurity (Harding et al., 2017), cystic fibrosis (Sullivan & Mascarenhas, 2017), and Rett syndrome (Leonard et al., 2013). In these cases, the goal of MNT is to provide extra calories and protein (as food or nutritional supplements) to achieve adequate weight gain and linear growth.

Poor Linear Growth and Low Bone Mineral Density

Typically, an important measure of sufficient nutrition in children is adequate linear growth. Yet, many developmental disabilities are associated with atypical growth patterns. As a result, it may be difficult to determine whether a child with a developmental disability who has apparent inadequate growth is truly undernourished (Marchand, Motil, & NASPGHAN Committee on Nutrition, 2006). Extra calories and nutrients may not normalize linear growth in certain medical conditions that are known to be associated with short stature, such as translocation chromosomal disorders, Turner syndrome, Down syndrome, Williams syndrome, chromosome 22q11 microdeletion syndromes (i.e., velocardiofacial syndrome and DiGeorge syndrome), meningomyelocoele (Liusuwan, Widman, Abresch, Styne, & McDonald, 2007), chronic kidney disease (Rodig et al., 2014), and fetal alcohol syndrome (Del Campo & Jones, 2017). These syndromes are described in Appendix B. Diagnosis-specific growth charts are based on smaller population groups than the standard growth charts for typically developing children, yet they help set realistic expectations for growth after a diagnosis has been made (Arvay et al., 2005).

If a child is consistently plotted below the 3rd percentile, it can be difficult to make comparisons over time. Growth charts that allow comparison of units of standard deviation from norms for reference age groups (z-score comparisons) are recommended when assessing growth and nutritional status in these children.

BOX 10.1 EVIDENCE-BASED PRACTICE**Gastroesophageal Reflux Disease**

Gastroesophageal reflux disease (GERD) is commonly seen in children with neurological impairment, with an incidence as high as 70% (Bayram et al., 2016). Gastroesophageal reflux (GER) involves the passage of gastric contents into the esophagus with or without regurgitation and vomiting. GERD occurs when GER leads to troublesome symptoms, which vary with age and degree of neurological impairment, and/or complications such as esophagitis, Barrett metaplasia, or esophageal stenosis (Rosen et al., 2018).

The diagnosis of GERD is based primarily on clinical suspicion, which can be strengthened by additional diagnostic investigations that aim to quantify and qualify GERD. A detailed history and physical exam should be obtained to assess “red flag” symptoms and signs that suggest an alternative underlying disease other than GERD that needs to be addressed and treated appropriately (Rosen et al., 2018). Objective testing for the diagnosis of GERD in children, such as esophageal pH or pH/multichannel intraluminal impedance monitoring, are useful to

1. Correlate persistent troublesome symptoms with acid and non-acid gastroesophageal reflux events
2. Clarify the role of acid and non-acid reflux in the etiology of esophagitis and other signs of symptoms suggestive of GERD
3. Determine the efficacy of acid suppression therapy

However, these tests can be difficult to perform in certain children with neurological impairment, and treatment for GERD may be started based on clinical suspicion.

Treatment for GERD involves nonpharmacological, pharmacological, and surgical options. Feeding modifications, including formula or food thickeners, reduced feeding volumes or more frequent feedings, and hydrolyzed or amino-acid based formulas, may improve some symptoms of GERD (Rosen et al., 2018). Feeding modifications should be carefully implemented based on the child’s neurological impairment, oral-motor skills, and feeding route. A 4- to 8-week trial of histamine-2 receptor antagonists or proton pump inhibitors with careful clinical follow up is also acceptable management in patients with neurological impairment (Romano et al., 2017). Laparoscopic antireflux surgery, mainly Nissen fundoplication, is currently accepted as the gold standard surgical procedure for children with severe, medically refractory GERD (Fukahori et al., 2016).

Points to Remember

1. Diagnosis of GERD is based on clinical suspicion. A detailed history and physical exam should be obtained to rule out alternative diseases that may present in a similar manner.
2. Nonpharmacological, pharmacological, and surgical treatments should be tailored according to patient’s symptoms, neurological impairment, and GERD-associated complications.

Table 10.3. Common nutrition advice that may not apply to children with disabilities

Common nutrition advice	How this advice may not apply to children with disabilities
“If she won’t eat now, don’t worry; she will eat when she is hungry.”	The child may not respond to hunger cues. Hunger may be masked by fatigue, medications, or specific medical conditions.
“Don’t worry. Others in the family are small.”	Genetic and hereditary factors are important to identify, but many “small” children with disabilities are often undernourished due to lack of sufficient intake.
“He’s just picky.”	Behaviorally based feeding problems are common in children with disabilities. Some food refusals are key symptoms of an underlying medical problem.
“He’s failing to thrive.”	Many disabilities are associated with atypical growth patterns (disability-specific growth charts allow for more accurate interpretation of growth patterns).
“He eats the same foods all the time. He should eat a variety of foods.”	Monotonous self-restricted eating patterns are common in children with developmental disabilities, especially those who have autism spectrum disorder. Some medical conditions (especially metabolic disorders) require a limited range of food types to prevent complications.

A z-score allows for quantification and longitudinal follow up of measurements that consistently fall above or below the upper limits of measurement on a growth chart (Becker et al., 2015). Total calorie deficit may not be the only cause for poor growth; protein and specific micronutrient deficiencies may also contribute to this problem (i.e., zinc, vitamin B₁₂, vitamin D, and iron).

Low bone mineral density is prevalent in neurologically impaired children, and it may affect linear growth (Romano et al., 2017). Limited ambulation, long-term administration of anti-epileptic drugs, reduced sun exposure, and poor nutrient intake are all factors that contribute to low bone mineral density. It is important to evaluate and optimize the child's bone health by providing an adequate intake of calcium, vitamin D, and phosphorus and promoting physical activity with the aid of a therapist (Golden, Abrams, & Committee on Nutrition, 2014). Children at risk for low bone mineral density should be evaluated using dual-energy radiograph absorptiometry (DXA) (Bianchi et al., & Clinical Society for Clinical Densitometry, 2013). Scans of the lateral distal femur are valuable for children with immobilization disorders or contractures who cannot be positioned for a spine or whole-body DXA (Bachrach, Gordon, & AAP Section on Endocrinology, 2016). Serum levels of 25-OH vitamin D, calcium, phosphorous, and parathyroid hormone also should be monitored.

Obesity

Children are also considered malnourished if they consume too much energy. Obesity is caused by excessive energy intake relative to energy expenditure and is typically defined, using the CDC growth chart, by a BMI greater than the 95th percentile for age. Notably, BMI includes assumptions about stature and body composition that may not be appropriate for certain children with disabilities. For example, **scoliosis** may interfere with accurate height measurements, which, in turn, can affect the calculation of the BMI. The American Academy of Pediatrics (Barlow & Expert Committee, 2007) provides guidelines for prevention, assessment, and treatment of overweight and obese children. Yet, some of these recommendations may not apply to children with neurological impairments who have varied levels of activity and different comorbidities that may affect food intake. Therefore, it is crucial to have serial monitoring of weight gain and screening for obesity-related complications including dyslipidemia, diabetes, hypertension, and nonalcoholic fatty liver disease in these children and adjust their nutritional care plan to prevent overweight and obesity. More research is needed

to better understand unique risk factors and interventions necessary to maintain a healthy body weight in children with developmental disabilities (Curtin, Must, Phillips, & Bandini, 2017). It is important to remember that cultural beliefs and practices may influence parental perceptions of their children's health status and feeding behaviors, and parents may have different definitions of what they consider to be "healthy." Assessing the family's knowledge and perceptions about health, social supports and networks, hunger cues, and healthful diets may assist health care providers in communicating health issues more sensitively and respectfully (Pena et al., 2012).

When Developmental Disabilities Limit Eating

Children with developmental disabilities may lack an appetite or have physical difficulties in eating. In these situations, mealtime, rather than being a pleasure, becomes an aversive experience for both the child and parents. It is thus imperative to identify the root causes of the eating problem and to design an appropriate therapy program. A child unable to eat because of fatigue and weakness resulting from a neuromuscular disability merits a different approach than a child who refuses to eat as a consequence of behavioral or cognitive issues. Children with dyskinetic cerebral palsy for instance may have such severe difficulty chewing and swallowing that they may risk aspiration pneumonia as well as undernutrition. In this case, nutritional therapy might be directed at providing alternative routes for nutrition, such as **gastrostomy** tube formula feedings (Romano et al., 2017). The child's risk of aspiration and degree of oral motor dysfunction can be studied by video-fluoroscopic assessment of chewing and swallowing function using different food and beverage textures and various feeding positions (Romano et al., 2017). A multidisciplinary team should perform careful assessment of feeding difficulties in children with developmental disabilities (Kerzner et al., 2015; see Chapter 29). Speech and language therapy and occupational therapy are often an important part of treating feeding problems.

Children with ASD may have severe and persistent restricted food preferences. However, a study by Edmond, Emmet, Steer, and Golding in 2010 showed that while children with ASD may have decreased variability in their diets, adequate energy intake is maintained, resulting in typical growth. Behavior management techniques may be utilized to gradually add new food items to the menu of the child with ASD (see Chapter 18). Such techniques may involve offering

rewards for trying new foods or encouraging the child to participate in food preparation.

MEDICAL NUTRITIONAL THERAPY

The overall goal of MNT is to achieve the child's growth potential and maintain adequate nutritional status. It is crucial to have a multidisciplinary team (physician, registered dietitians, nurse, social worker, and occupational and speech therapists) that works with the family to assess the child's underlying medical condition and nutritional status and develops an individualized plan for nutritional interventions that optimizes the child's health.

Nutritional Assessment and Care Plan

The tools of MNT are the nutritional assessment and care plan that is customized to the needs of each child. A nutritional assessment usually answers the following questions:

1. Is the child being fed a diet that meets his or her nutritional requirements?
2. Is the child growing as expected for his or her age, gender, and condition?
3. Is there a feeding or eating problem interfering with growth or with meeting nutritional requirements?
4. Does the child require alternative means of nutritional support? (Riddick-Grisham, 2004, p. 328)

The nutritional assessment is the first step in the process of documenting a child's status. This involves the steps outlined in Table 10.4; the measurement and interpretation of growth parameters are defined in Table 10.1. If a child's nutritional status is not optimal, recommendations are made to improve the diet and feeding or eating practices.

Table 10.4. Elements of a nutrition assessment

Review the child's medical history (including diagnosis, laboratory findings, medications used, and developmental levels).
Assess and interpret the child's growth parameters (see Table 10.1).
Obtain the child's dietary history from caregivers (including intake patterns for food and drink, portion sizes, meal duration, and use of supplements).
Analyze and interpret the dietary intake information, based on the child's age and gender, for macronutrients (protein, fats, and carbohydrates), micronutrients (vitamins and minerals), fluids, and other dietary components (e.g., dietary fiber); computer dietary analysis programs can be used.
Summarize impressions of the child's nutritional status and the adequacy of his or her diet; make recommendations and referrals.

The nutrition care plan articulates recommendations and spells out monitoring and follow-up needs. Table 10.5 shows common interventions found in a nutrition care plan. In addition to offering general dietary and feeding recommendations, a well-developed nutrition care plan addresses the role of food in the family life and in its culture, taking into consideration their meal and snack patterns, food choices, and food preparation. When estimating daily energy requirements, it should also take into account that parents may overestimate or overreport a child's caloric intake. For children with cerebral palsy, their nutrition care plan should account for calorie losses due to gastroesophageal reflux or retained exaggerated infant reflexes like tonic bite, tongue, or jaw thrust. Furthermore, plans should factor in a child's degree of neurological disability, mobility, feeding difficulties, mode of nutritional support, and the need for weight gain or weight loss (Shaikhkhalil & Meyers, 2015). Decreased activity may lead to overnutrition, especially in children who are fed by feeding tube. Lower calorie formulas with adequate protein and micronutrients should be used instead of diluting the formula. If obesity is a family problem, the weight loss plan should involve changing the entire family's eating patterns. If the family culture involves ingesting fatty and fried foods, a plan should be developed with the family to incorporate different cooking patterns. When providing food is equated by the parents to providing love, emotional needs may

Table 10.5. Sample interventions found in a nutrition care plan

Analyze and interpret home intake diet record.
Recommend meal and snack schedules or timing.
Counter side effects from medications (e.g., increased appetite, effect on taste).
Prevent overweight or underweight.
Monitor planned weight gain, weight loss, or catch-up growth.
Modify diets for specific nutrients, such as low protein, high calorie, or low fat.
Reinforce breast feeding, infant formula, or formula preparation steps.
Select foods to address food texture problems or avoid choking.
Manage food refusals, food jags, or other food behaviors.
Demonstrate how to determine portion sizes and measure foods.
Order special formulas or supplements.
Reinforce signs of hunger, fullness, and right pace of eating or feeding.
Document food insecurity and refer the family to community nutrition programs.
Coordinate with other health care providers and educators.
Complete referrals for the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) as well as for early intervention services or other providers.

be interfering with appropriate nutritional intake. If food is used as a behavioral reinforcer, another equally effective non-food reinforcer (e.g., attention) may need to be identified and implemented.

Methods of Nutritional Support

Oral food is the preferred method of feeding children. However, some children may require enteral nutritional support. Enteral tube feeding is necessary in children who 1) cannot meet their energy, fluid, or nutrient needs orally; 2) are at risk for aspiration; 3) have oral motor feeding difficulties; or 4) have difficulties with medication administration (Monczka, 2015; see Box 10.2 for more examples). The most common developmental disabilities that require nutritional support include cerebral palsy (e.g., spastic quadriplegia), progressive neurologic disorders (e.g., Tay-Sachs disease), poorly controlled seizure disorders (e.g., Lennox-Gastaut syndrome), and certain inborn errors of metabolism (e.g., urea cycle disorders) (Monczka, 2015). Current clinical and nutritional status of the child, length of time enteral feedings are likely to be required, and the type of feeding regimen that may best fit the needs of the child and family should be considered when determining the type of enteral access (Shaikhkhalil & Meyers, 2015). Nasogastric tube feeding is used for short-term nutritional support (less than 12 weeks) or in children who are awaiting gastrostomy tube placement. A gastrostomy tube can be placed surgically or

endoscopically; it allows direct access to the stomach through the anterior wall and direct enteral administration of feedings (Abdelhadi, Rahe, & Lyman, 2016). Gastrostomy tube feeding can help bypass some eating difficulties and decrease the family's psychological stress around nutritional issues. Children at high risk for aspiration due to neurologic or swallowing dysfunction, anatomical abnormalities, or gastrointestinal dysmotility may benefit from tube feedings that bypass the stomach (i.e., gastrojejunal, also called GJ-tubes). It is crucial to provide detailed education to the child's family and other caregivers about feeding tubes and site care (Table 10.6; Abdelhadi, Rahe, & Lyman, 2016).

Establishing a feeding regimen to optimize a child's nutritional status requires assessment of 1) the child's medical condition, 2) the goal of growth rate, 3) the previous history of feeding tolerance, and 4) the family's daily schedule. Multiple bolus feedings (a set amount of nutrition given via nasogastric or gastrostomy tube over a short period of time) throughout the day is the preferred enteral feeding regimen as opposed to continuous feedings. This simulates the physiological response to feeding and allows for a convenient and flexible schedule for caregivers. For some children with bolus feeding intolerance (marked by abdominal distention or discomfort, vomiting, or frequent regurgitation) resulting from delayed gastric emptying or for children at high risk for aspiration, continuous postpyloric feedings or jejunal feedings may be required (Abdelhadi, Rahe, & Lyman, 2016; Shaikhkhalil & Meyers, 2015).

BOX 10.2 INTERDISCIPLINARY CARE

The Multidisciplinary Care Team of a Child Receiving Enteral Tube Feedings: Role of the Nurse

A multidisciplinary team approach is critical when managing the care of a child who receives feedings delivered by enteral tube, typically including involvement by a physician, nurse, occupational therapist, speech therapist, physical therapist, registered dietitian, and pharmacist. The nurse plays a particularly important role in this team and provides the following care:

- Teaches home and school caregivers how to prepare and administer enteral formula
- Provides emotional support for caregivers, identifying family stressors and anxiety associated with tube feeding
- Provides coordination and technical support while teaching about enteral access device placement, management, and troubleshooting if problems arise
- Assesses the health literacy of the caregiver and comprehension of information, adjusting the delivery of information if needed
- Works with caregivers to understand and use formula delivery methods like enteral pumps
- Works to balance calories consumed orally with those delivered enterally, especially when a child is transitioning off enteral feedings
- Communicates with home caregivers regarding changes in the feeding plan

Table 10.6. Feeding tubes care and troubleshooting issues

Feeding tube	Site care	When to be concerned
Nasogastric	Secure the tube to the child's face with hypoallergenic adhesion products. Fix excess tubing to the back of the child to keep out of sight and prevent accidental dislodgement.	1. Vomiting with feedings. 2. Increase in abdominal distention. 3. Respiratory distress during feedings. 4. Yellow drainage from the nostril (move the tube to the opposite nostril and assess for sinusitis).
Gastrostomy	Wash skin with soap and water. Keep area dry and clean. Rotate tube once or twice daily. Replace with a new tube every 12 weeks after health provider has done first tube change.	1. Dislodgement: Management is based on the time from placement. 2. Pain with feeds could indicate an infection or misplaced tube. 3. Erosion, erythema, and induration of the surrounding skin. 4. Increase in abdominal distention—may vent the gastric port to allow air to come out to alleviate distention. 5. Respiratory distress during feedings.
Gastrojejunostomy	Wash skin with soap and water. Keep area dry and clean. Never rotate. Provide continuous formula drip only via jejunal port.	1. Same as above. 2. Vomiting formula could indicate jejunal port has migrated back to the stomach.

Table 10.7 provides a sample dietary intake for a child with spastic quadriplegia who receives a combination of oral, bolus, and continuous feedings via a gastrostomy tube.

Nutrition Support Formulas

A wide range of formulas are available as food replacements, food supplements, and nutrition support as described in Table 10.8. These differ from infant formulas in terms of energy content, **osmolality** (concentration of a solution), and the level of supplemented vitamins and minerals. Nutrition support formulas differ from one another in specific nutrients, caloric density, intended use, and mode of administration. Children older than 1 year of age who require nutritional supplementation

may be transitioned to pediatric formulas (intended for children up to 10 years old) that provide 30 calories per fluid ounce as compared with regular infant formulas that provide 20 calories per fluid ounce. Children older than age 10 may use a formula intended for adults (Joeckel & Phillips, 2009). Protein-free or carbohydrate-free formulas employed in inborn errors of metabolism entail additional arrangements (see Chapter 16). They cannot be used alone as they create a nutritional deficiency; they need to be mixed with other formulas or foods (Isaacs & Zand, 2007).

SPECIAL NUTRITIONAL CONCERNS IN CHILDREN WITH DISABILITIES

Children with developmental disabilities may require specialized diets to address nutritional concerns associated with their disability. Common nutritional concerns associated with specific developmental disabilities are listed in Table 10.9. In most cases, families of children with specialized diets benefit from the involvement of a registered dietitian who can help monitor the diets and provide consultative support to schools and other agencies. A multidisciplinary team, which should include a nurse, dietitian, and pharmacist, among other professionals, will ensure appropriate implementation of dietary recommendations.

Therapeutic Diets

Low-protein diets, used for certain inborn errors of metabolism, and the **ketogenic diet**, used in some children with intractable epilepsy, provide examples of customized diets that differ in composition and goals.

Table 10.7. Sample intake and feeding schedule for a child with a limited ability to eat by mouth and supplemented feedings via gastrostomy tube

6:30 a.m.	Stop night feeding pump
9:30 a.m.	Oral snack at school: milk in a cup and spoon-fed applesauce
11:45 a.m.	School lunch: modified soft texture, 30% self-feeding
1:00 p.m.	Gastrostomy feeding of 8 fluid ounces of complete nutritional supplement
3:30 p.m.	After-school snack at home: self-fed cookie and milk in a cup
6:00 p.m.	Supper with family: mashed potato with gravy on a spoon and juice in a cup
8:30 p.m.	Start night feeding of 50 milliliters per hour complete nutritional supplement, providing 40% of daily calories and 60% of daily protein intake

Table 10.8. Selected formulas for children with disabilities

Formulas and their components	Use based on diagnosis or condition
Standard infant formulas; 20 calories per fluid ounce ^a	Full-term newborns up to 1 year
Premature transitional formula; 22 calories per fluid ounce ^a	Discharge formula for infants with birth weight of < 1,800 grams, on limited volume intake or a history of osteoporosis or poor growth
Complete nutritional supplements; 30 calories per fluid ounce ^a	Meal or snack substitutes Increase calories Ensure intake of specific nutrients (e.g., protein)
Formulas modified in the balance of nutrients; these are not used alone	Protein free: protein-restricted diets Carbohydrate restricted: ketogenic diet Fat altered: diets for gastrointestinal disorders or long-chain fatty acid oxidation disorders Specific amino acids removed: phenylketonuria

^aCalories per fluid ounce can be adjusted based on a child's needs.

Table 10.9. Common nutrition concerns of particular developmental disabilities

Prematurity-related nutrition problems, likely in the first 3 years	Formula changes to accommodate medical problems Delayed self-feeding and oral-motor dysfunction Rate of growth corrected for preterm birth Difficulty with setting feeding schedules Variable appetite, especially with illness Gastrointestinal problems (constipation, gastroesophageal reflux, reduced appetite, milk protein allergy)
Neuromuscular disorders (e.g., spinal muscular atrophy)	Difficulty gaining weight, particularly with frequent illness Excessive weight gain due to immobility and high calorie intake Underweight with low muscle mass Short stature Gastrointestinal issues (constipation, gastroesophageal reflux, gastroparesis) Feeding difficulties or oral-motor dysfunction limiting food types Need to consider supplementation or gastrostomy tube placement Unusual growth patterns
Developmental delays/intellectual disability (e.g., Down syndrome, Prader-Willi syndrome)	Underweight or overweight Unusual level of activity, either higher or lower Delayed self-feeding skills Self-restricted diet Difficulty identifying hunger and fullness Constipation, which may or may not be alleviated with dietary fiber
Attention-deficit/hyperactivity disorder	Distractibility interfering with eating and sitting during meal times Lack of structured meal and snack patterns Possible decreased appetite as a medication side effect
Epilepsy	Difficulty with socializing at meals A growth plateau is likely, even if eating well Possible changes in appetite as medication side effect A post-seizure state is likely to interfere with meals and energy intake Unusual growth patterns in children with poorly controlled seizures

Both types of diet are similar in that they require close monitoring and may cause behavior problems around food at home, in school, and at restaurants. Table 10.10 shows a sample daily nutritional intake for a 10-year old with phenylketonuria (PKU) who is complying well with a low-protein diet.

As a result of the effectiveness of early dietary treatment for PKU, the list of inborn errors of metabolism treated early in life through diet has increased markedly (Evans, Truby, & Boneh, 2017; Frazier et al., 2014; Singh et al., 2013). As newborn screening and knowledge of dietary interventions expands, the focus has shifted toward developing evidence- and consensus-based guidelines for nutritional management of inherited metabolic disorders, with a goal of optimizing longer-term outcomes for patients (Singh, Rohr, & Splett, 2013; Osara et al., 2015).

Another example of medical treatment through dietary modification is shown in Table 10.11, which presents a sample dietary intake for an older child on a ketogenic diet. A ketogenic diet is deliberately designed to be very high in fat content and very low in carbohydrates, while providing adequate calories and protein for growth. This diet results in the accumulation of ketones in the body; ketones are thought to be the mechanism of improved seizure control (see Chapter 22). The sample diet shown is for an older child who eats regular foods; however, some children on the ketogenic diet are not able to consume food by mouth and rely on specific fat-modified formulas that are administered through a gastrostomy tube (Zupec-Kania & Spellman, 2008).

Table 10.10. Sample diet for a 10 year old with phenylketonuria (PKU)

Breakfast	1/2 cup cereal 6 fluid ounces rice milk 1 low-protein blueberry muffin 8 fluid ounces PKU formula
Lunch	Medium garden salad with 2 tablespoons of ranch dressing Small order of french fries 12 fluid ounces non-diet soft drink
After-school snack	Baked apple slices with brown sugar and cinnamon 8 fluid ounces PKU formula
Dinner	Hot dog bun with 1 slice low-protein cheese, mustard, ketchup, and pickles Pear 8 fluid ounces PKU formula

Table 10.11. Sample ketogenic diet: Intake for an older child on a 4-to-1 (fat-to-protein plus carbohydrate) ratio

Breakfast	Omelet made with 35 grams egg, 35 grams butter, 20 grams mushroom
Lunch	55 grams beef bologna 15 grams black olives 30 grams mayonnaise 20 grams tomato
After-school snack	Carbohydrate-free multivitamin and mineral pill 20 grams strawberries 55 grams heavy whipping cream
Dinner	25 grams chicken breast cooked in 25 grams butter 25 grams avocado 25 grams green beans cooked in 20 grams butter
Snack	50 grams carrot sticks 25 grams mayonnaise

Food Allergies

While there is not a clear linkage of food allergies to developmental disabilities, food allergies are common in the general population, and, as such, are also prevalent in children with disabilities. A food allergy is an adverse reaction to food caused by an immune response. The most common food allergens in the United States are milk, soy, egg, wheat, peanut, tree nut, fish, and seafood. Poor nutritional outcomes may occur in children with food allergies as a consequence of diet restrictions that may severely impact nutrient intake. Nutrition education should focus on foods to be avoided. Nutritionally complete hypoallergenic formulas are available to supplement a child's intake and ensure adequate growth (Meyer et al., 2016). Eosinophilic esophagitis (EoE) is a specific type of allergy in which inflammation of the esophagus may lead to feeding aversion or picky eating. EoE is one of the most common conditions diagnosed during the assessment of feeding problems in children (Furuta & Katzka, 2015).

Constipation

Gastrointestinal dysfunction is a frequent concern for children with developmental disabilities. Immobility, low enteral fluid intake, and medication side effects are all factors that contribute to constipation, especially in children and adults with cerebral palsy. Increasing dietary fiber by substituting whole wheat bread for white bread and fresh unpeeled apples for apple juice, are often suggested to families dealing with children

with disabilities who are fed by mouth. For tube-fed children, providing a fiber-containing formula and additional fluid in the form of free water via gastrostomy or jejunostomy tube may alleviate constipation. Constipation that is refractory to increasing fiber in the diet can be treated using stool softeners or stimulant laxatives (lactulose, polyethylene glycol or milk of magnesia, bisacodyl, or senna; Tabbers et al., 2014).

Celiac Disease

Celiac disease may present with symptoms of diarrhea, abdominal pain, anemia, constipation, or poor growth. Celiac disease involves a permanent sensitivity to gluten, the protein portion of wheat and rye. Some children with celiac disease also have to avoid oats. Children with Down syndrome, Turner syndrome, and Williams syndrome have a higher incidence of celiac disease than children in the typically developing population (Hill et al., 2016). In affected children, a gluten-free diet has to be followed strictly, even when children are asymptomatic. The North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (Hill et al., 2016) provides detailed guidelines for the evaluation and chronic management of children with celiac disease. Many processed foods from both grocery stores and restaurants must be avoided because they contain wheat and other flours for fillers and binding agents. Potato-, soy-, and rice-based products can be used as substitutes for regular breads and pastas, although these specialized foods may be prohibitively expensive for many families.

Dietary Self-Restriction

Dietary self-restriction is a common problem in children with developmental disabilities, manifesting as food refusal, selectivity by type of food or food texture, oral-motor delay, and **dysphagia** (see Chapter 29). As noted previously, ASD is particularly associated with a selective eating pattern (Hyman et al., 2012; Kerzner et al., 2015). Sensitivities to food colors, textures, and temperature are often reported as leading to food refusal. When not given preferred foods, the child completely refuses to eat and may have temper tantrums. The child may also prefer to drink rather than to eat foods, and so a high proportion of total calories may come from one type of drink. Interventions to improve the child's diet may include providing a complete vitamin and mineral supplement and adding new foods one at a time, offering them many times (15 to 20 times) over 1–2 months paired with positive reinforcers (i.e., foods the child likes; see Chapter 34). Usually children

with ASD have typical growth and caloric intake despite their unusual eating habits.

NUTRITION WITHIN COMPLEMENTARY HEALTH APPROACHES

In response to the large number of children with developmental disabilities, many products, treatments, and medicines have been created to improve nutrition. Products claiming to boost energy or correct nutritional deficiencies are especially attractive to parents. Data from the 2007 National Health Interview Survey show that one in nine children used **complementary health approaches (CHA)** in 2006 (National Center for Health Statistics, 2008b; see Chapter 39). Most parents who use CHA for their children do not spontaneously share that information with their care provider. It is important that providers inquire about the use of CHA and be aware of potential interactions of various supplements with medications or other aspects of care (Shaikhkhalil & Meyers, 2015). In the developmental disability population, the use of CHA is most commonly associated with attention-deficit/hyperactivity disorder, ASD, and cerebral palsy. CHA approaches that are promoted to improve nutrition include **megavitamin therapy**, amino acid and mineral supplements, and herbal remedies. Although CHA approaches are often presumed to be harmless, the safety of these approaches has not been well documented, and no CHA nutritional therapy has been proven effective by scientific methods (Kemper, Vohra, Walls, & the Task Force of Complementary and Alternative Medicine and the Provisional Section on Complementary, Holistic, and Integrative Medicine, 2008). CHA in the form of nutritional supplements can lead to an increased risk for or new side effects of medication received to control the underlying disability (e.g., antiepileptic drugs). Thus, a child's medical and nutrition history should include a comprehensive list of supplements (Kemper et al., 2008).

SUMMARY

- Underweight, overweight, constipation, food allergies, feeding difficulties, and other gastrointestinal disturbances that interfere with appetite are more common in children with developmental disabilities than in typically developing children.
- Typical dietary guidelines for Americans (U.S. Department of Agriculture, 2010) and the MyPlate plan (U.S. Department of Agriculture, n.d.) are not sufficient resources for customizing nutrition recommendations for many children with developmental disabilities.

- Medical nutritional therapy that includes a nutritional assessment and care plan should be part of the comprehensive care for children with developmental disabilities.

PART III

Developmental Assessment

CHAPTER 11

Child Development

Louis Pellegrino

Upon completion of this chapter, the reader will

- Define *child development* and key terms related to this concept
- Describe the various theoretical perspectives on child development
- Explain the uses and potential misuses of developmental milestones
- Discuss trends in child development with reference to the concept of human adaptability
- Distinguish between typical and atypical development
- Explain the importance and uses of developmental surveillance and developmental screening

Most people are familiar with the concept of child development, at least in a general sense. They know that dramatic changes in appearance, behavior, and ability characterize childhood, and many have at least a vague memory of having gone through these processes. It can be more difficult to define development in precise terms and especially problematic to clarify what is meant by terms such as *typical* or *normal* with reference to the processes of development.

This chapter addresses these issues and provides a basis for the discussions on diagnosing developmental disabilities in subsequent chapters.

■ ■ ■ CASE STUDY

Isabella is a 2-year-old girl from a bilingual family; both Spanish and English are spoken in her home. She is seen 1 week after her second birthday for a well-child visit. Her pediatrician, who is also bilingual, asks

Isabella's mother if she has any concerns. Isabella's mother feels that her daughter is growing well, has been healthy, and has a cheerful disposition, but she is concerned that her daughter is not talking yet. Isabella seems to understand most of what is said to her (in Spanish and English) and is surprisingly adept at making her needs and wants known through the use of pointing, vocalizing (especially grunting), eye gaze, eye contact, and "body language." Although she doesn't use recognizable words, she speaks a kind of "gibberish" that occasionally sounds vaguely like real words. She recognizes and responds to her name, can identify a few body parts and pictures in books by pointing, and can respond to simple instructions, such as "go get your coat." She walks and runs well, is learning how to jump, can use a spoon and a fork, pretends to feed her stuffed animals, and has developed an independent streak, with occasional tantrums when she doesn't get what she wants.

Isabella's pediatrician decides to administer a developmental screening test, which consists of a series of simple questions answered by Isabella's mother. The screen reveals that Isabella "passes" in all areas, except language development. Although her mother is sure that Isabella hears well, the pediatrician recommends that Isabella have her hearing tested by an audiologist. She also refers Isabella to the local early intervention team to further assess her development and determine if she is eligible for home-based speech therapy.

Isabella's mother wonders if speaking two languages at home might be confusing to Isabella; relatives have told her that she should only speak to Isabella in English. The pediatrician reassures her that living in a bilingual home does not cause language delays and that, in the long run, being bilingual confers significant developmental and cognitive advantages.

Thought Questions:

How might some developmental milestones be more useful in some clinical situations more than others? How can atypical development be distinguished from variations in typical development?

DEFINING CHILD DEVELOPMENT

Development in a generic sense can refer to anything that changes over time (e.g., a photographic negative develops), but it most often describes an organic process of change. For the purposes of this book, the term *development* is used with reference to changes in human thought, behavior, and function. Development is distinguished from the term *growth*, which refers more specifically to physical increases in height, weight, head size, and sexual maturation. Although the concepts of growth and development are obviously connected, the techniques used to measure and describe them tend to be separate.

As applied to the individual human being, the term *development* can possess different meanings. On the one hand, a person changes in response to a specific set of life circumstances and experiences. In this sense, every human being has a unique developmental history that can never be replicated. On the other hand, individuals experience changes in cognition, emotion, and specific abilities that likely indicate a common "blueprint" that transcends individual life histories or cultures. For example, walking is begun and mastered at about the same age and seems to follow a fairly consistent sequence across cultures. Similarly, children universally and spontaneously learn to speak their

native languages and do so in a predictable sequence of steps without any explicit instruction in vocabulary or grammar.

Additional general changes in behavior and social-emotional responses also occur on a predictable timeline and in predictable ways. Typically, infants begin to exhibit "stranger anxiety" at about 6 or 7 months of age, toddlers demonstrate limit-testing behavior as part of increasing autonomy, school-age children become enamored of rules and enjoy a sense of industrious accomplishment, and preteens and teens experience a sense of independence and identity in the context of intensified peer relations.

Human development is wonderfully varied but reasonably predictable and, for the purposes of this discussion, may be defined as follows: *Development* refers to the characteristic, predictable ways in which behavior changes during the human life cycle. At its most basic level, *behavior* refers to any action that a person can perform and another can observe. Moving a leg, sneezing, saying a word, and composing a symphony are all forms of human behavior. Behavior can be characterized as simple (moving an arm) or complex (playing a concerto). Some forms of behavior are inherently more meaningful than others (e.g., talking versus coughing). With regard to the definition of development, behavior that is most directly relevant to real-life situations tends to be of greatest interest (e.g., identifying pictures in a book, using a spoon, or riding a bike). Behavior is also used as a proxy for aspects of cognition and emotion that are critically important to development but that cannot be observed directly (for example, using shape drawing as a proxy for one aspect of nonverbal cognition). Observing and interpreting behavior is, in fact, the primary focus of developmental assessment.

In everyday speech, the word *normal* usually describes something that is usual or expected. For example, "The weather is normal for this time of year," means that the temperature, humidity, and presence or absence of precipitation is close to average or to be expected based on previous experience. Saying the weather is normal doesn't necessarily convey a value judgement. People speak of "bad weather" with regard to a damaging thunderstorm, but such a storm might be normal for the peak of summer in a particular area.

When referring to human development and behavior as normal or abnormal, the message does tend to carry good or bad connotations. For example, when a parent scolds a child for misbehaving, and asks, "Why can't you act *normal*?" the parent is really saying that the behavior is not only different from what is expected but that it is also bad. Saying that a child's speech development is abnormal also implies, perhaps

more subtly, that there is something bad or wrong with that child's speech.

In discussions of behavior and development, it is therefore preferable to use the term *typical* to express the idea of usual, expected, or average and *atypical* to convey that which is unusual, unexpected, or significantly different from average. Although these terms are also less than perfect in avoiding value judgment (in particular, the word *atypical* does have at least a mildly negative connotation to most ears), they are still preferable to *normal* and *abnormal* and seem to be the best options, especially when attempting to emphasize a child's abilities rather than disabilities.

THEORETICAL PERSPECTIVES ON DEVELOPMENT

Several theoretical perspectives help practitioners and families understand child development, including those concerning the brain (biology, maturation, and cognition), the environment, and social context. Key theories are summarized in Table 11.1.

A common theme of all developmental theories is the idea of adaptation. Each theory in its own way considers development to be an adaptive response of the human organism to its environment. The dynamic systems theory (Thelen & Smith, 1994) is a striking example of this. This theory draws on mathematical concepts of dynamic systems and considers behavioral change as an emergent property of an organism in a specific environmental context. Developmental sequences, rather than being rigidly predetermined, are seen as processes of dynamic change of a specific organism to a specific set of circumstances organized around a specific task. For example, a child with specific physical characteristics who tries to pull herself up to a standing position using the edge of a coffee table is exhibiting an adaptive response.

The Brain

Development is dependent on the brain, and the predictable behavioral changes that characterize development occur in parallel with the maturation of the central nervous system. Functional and structural changes in the human nervous system are most dramatically evident during fetal life and early childhood but continue into adulthood (see Chapters 6 and 8). These processes promote and are intimately connected to developmental change. For example, myelination of key **corticospinal pathways** (pathways from the cortex of the brain to the spinal cord that orchestrate movement) during

the first year of life is one of the main determinants of early gross motor development, such as rolling over, sitting, and crawling (Volpe, 2018). Critical changes in the brain's functional organization occur toward the end of the second year of life that create an opportunity for explosive language development that typically occurs between 18 and 24 months of age (Redcay, Haist, & Courchesne, 2008).

Changing nervous system **plasticity** (the ability of the nervous system to change or adapt) over the course of the human life cycle also creates opportunities and constraints on development. One example of this phenomenon is the well-known observation that young children much more easily attain fluency in a foreign language than do adults or older children (i.e., beyond 8 or 9 years of age). Indeed, there appears to be a sensitive period for language acquisition during these early years, and children who miss this opportunity will most likely never develop fluency in any language (Werker & Hensch, 2015). The good news for adults is that although there is decreased brain plasticity with age, learning continues unabated through the entire life cycle. The brain works by creating a rich network of functional connections within and across many cortical and subcortical domains, and these networks are continually enhanced and elaborated throughout the life span.

Biology, Maturation, and Cognition

A number of developmental theories have emerged during the 19th and 20th centuries in an attempt to provide an explanatory framework for the processes of developmental change. Of these, Sigmund Freud's theory of psychosexual development is one of the best known and perhaps most notorious (Freud & Strachey, 2000). Freud viewed the conflict between in-born biological drives and external societal restrictions as being the engine of developmental and behavioral change. Although most of the specifics of his theories are no longer accepted, his idea of development as occurring in a series of stages, each dependent on the one before, has had a lasting influence.

Erik Erikson's psychosocial stage theory (Erikson & Coles, 2000) has given us a model for development through the life span that describes a series of existential crises that must each be successfully overcome. The most famous of these is the identity crisis of adolescence, and the idea of a "midlife crisis" in popular usage also stems from Erikson's ideas.

Other development theories have focused on the biological underpinnings of developmental change. Attachment theory, for example, emphasizes the critical importance of the infant-caregiver bond and describes early infancy as a critical period within which such

Table 11.1. Developmental theories in a nutshell

Theory	Focus	Key components
Theories emphasizing biological and maturational factors		
Gesell: Maturational theory of development (Shaffer & Kipp, 2014)	Genetically determined blueprint for development unfolds in specific sequences	Definitions of specific sequences of development and recognizable, testable milestones form the basis of subsequent screening/testing
Freud: Psychosexual stage theory (Freud & Strachey, 2000)	Conflict between biological drives and societal restrictions generates developmental change	The psyche is classified into domains (id, ego, superego) and stages of personality development are defined (oral, anal, phallic, latent, genital) based on interactions and conflicts among the domains
Erikson: Psychosocial stage theory (Erikson & Coles, 2000)	A series of psychosocial crises drives development (also has a maturational/psychosexual orientation as an offshoot of Freud's theory)	Eight stages are defined (trust, autonomy, initiative, industry, identity, intimacy, generativity, integration) in relation to their opposites; at each stage a crisis (e.g., identity crisis in adolescence) is faced, allowing the person to advance to the next stage
Bolby: Attachment theory (Bowlby, 2005)	Infants are born with an innate need to form attachments with caregivers to ensure survival	Child-parent interactions yield different patterns of attachment (secure, insecure, anxious) that result in different developmental and behavior outcomes
Ethology and evolutionary psychology (Shaffer & Kipp, 2014)	Behavior and development are explained in terms of evolutionary adaptation	Behavioral analogies to other animal species (especially primates) in conjunction with information from paleontology and anthropology inform theories regarding current human development and behavior
Theories emphasizing cognitive factors		
Piaget: Cognitive development stage theory (Wadsworth, 2004)	Cognitive processes and ways of thinking are constructed through interactions with the environment	Stages are defined (sensorimotor, pre-operational, concrete operational, formal operational) based on the manner of thought that characterizes each stage, starting with basic motoric responses to sensory stimuli and ending with abstract thought
Information processing theory (Shaffer & Kipp, 2014)	Model based on analogy to computer processing	Cognition develops through modifications to the information-processing machinery of the brain
Theories emphasizing environmental factors		
Behavioral theories of child development (Shaffer & Kipp, 2014)	The child is a blank slate that is shaped through behavioral conditioning	Environment determines behavior and development through association, conditioning, and reinforcement (e.g., behaviors associated with rewards are reinforced)
Bandura: Social learning theory (Bandura, 1977)	The social context is critical to learning	Conditioning and reinforcement alone cannot explain behavior; social observation and modeling lead to learning and the acquisition of new skills
Theories emphasizing social and cultural factors		
Vygotsky: Sociocultural theory (Vygotsky & Cole, 1978)	Learning is inherently a social process	Development occurs through active, hands-on engagement in activities of increasing difficulty and complexity with family and peers facilitating (scaffolding) the process
Bronfenbrenner: Ecological theory (Bronfenbrenner, 1979)	The cultural context drives development	Nested developmental settings starting from those closest to the individuals (e.g., home, school) and extending to broader societal settings (the culture with its laws, history and traditions) determine the roles, activities, and relationships that drive developmental change
Theories emphasizing processes of adaptation		
Dynamic systems theory (Thelen & Smith, 1994)	Mathematical concepts of dynamic systems applied to developmental change	Behavioral change and development are emergent properties of complex systems that include the individual, the environment, and multiple particular elements of each that are in constant flux

bonds must form (Bowlby, 2005). Arnold Gesell saw genetics and neurology as providing a blueprint for developmental change and focused on mapping these changes by identifying easily observable and testable milestones. His work has had a lasting influence on developmental screening and testing procedures. Ethological theories have taken an evolutionary perspective on development and behavior and have drawn on observations of other primate species for analogies to human behavior (Shaffer & Kipp, 2014).

One of the most influential developmental theories is Piaget's cognitive development stage theory (Wadsworth, 2004). Piaget proposed that our interactions with the environment are governed by the construction of cognitive processes during childhood, which he called schemas. These schemas arise through processes of adaptation to the environment, which he referred to as assimilation (processing information using existing schemas) and accommodation (creating new schemas to process new types of information). The first stage (sensorimotor) provides the foundation by connecting sensory perceptions to motor responses via the construction of cognitive intermediaries. Subsequent stages (pre-operational, concrete operational, and formal operational) elaborate on these cognitive structures to provide an increasingly complex and abstract means of responding to the world around us.

Selma Fraiberg drew on Piaget's description of the pre-operational stage of development to describe the charming idiosyncrasies and "magical thinking" of the preschool years in her influential work, *The Magic Years* (Fraiberg, 2015). The interest of school-aged children in rules and in understanding how things work through the use of basic logic is explained in Piaget's theory as manifestations of the concrete operational stage of development. The turbulence of the adolescent mind as it struggles to grapple with existential realities and abstract ideas is explained in Piaget's theory as a manifestation of the formal operational stage of development.

In recent years, information processing theory, a concept of cognitive psychology, has emerged to reemphasize the importance of cognitive processes in development and behavior. The theory draws heavily on analogies to computer processing to create a modular scheme of human cognition with a strong emphasis on the basic mechanisms of attention, memory, and learning (Shaffer & Kipp, 2014).

The Environment and Social Context

Other developmental theories (see Table 11.1) have emerged to emphasize the importance of the environment in developmental change. Behavioral theories

of development have emphasized the importance of environmental contingencies in reinforcing some behaviors preferentially, especially through the association of preferred behaviors with rewards (e.g., receiving parental praise for good behavior). The most radical behavioral model, B. F. Skinner's operant conditioning theory, considers a child to be a "blank slate" whose behavioral responses are entirely governed by these environmental contingencies (Skinner, 1966). Although this form of the theory has not stood the test of time, behavioral principles have had a lasting impact in clinical practice, where they have provided the basis for a variety of therapies such as applied behavioral analysis to address maladaptive behaviors (see Chapter 34).

Other theories have emphasized the social and cultural context of learning and development. Social learning theory (Bandura, 1977) emphasizes the importance of social modeling and imitation in learning. Vygotsky's sociocultural theory (Vygotsky & Cole, 1978) emphasizes the importance of family, teachers, and peers in facilitating hands-on learning. He introduced the concept of the **zone of proximal development**, which represents the space between what learners can do on their own and what they are not ready to do at all; it is the place where or circumstances within which children are able to learn new, difficult things with the help and support of others. Because of its clarity and utility, Vygotsky's theory has had a lasting influence on educational practices and teacher training. Bronfenbrenner's ecology theory (Bronfenbrenner, 1979) emphasizes the cultural context and the roles, activities, and relationships engendered by that context that determine individual behavior to a greater or lesser degree.

DEVELOPMENTAL MILESTONES

Developmental theory can offer a framework for thinking about developmental processes, but it is necessary to find a way to operationalize the discussion of typical development by invoking the concept of the developmental milestone. Simply defined, a **developmental milestone** is a behavior, ability, or skill that emerges at a particular age in most children and which can easily be observed and described. For example, most children take their first independent steps at approximately 12 months of age (Figure 11.1). Of course, some children start a bit earlier than this and others a bit later. About 90% of children have started taking independent steps by about 14 months of age, and so children who start walking after this age are considered "delayed" for this milestone (Piper & Darrah, 1994).

Figure 11.1. Milestone: early stepping. 50% of children take their first independent steps by 11 months; 90% have achieved this milestone by 13.5 months. (Adapted with permission from Piper, M.C., & Darrah, J. [1994]. *Motor assessment of the developing infant* [p. 165]. Philadelphia, PA: W.B. Saunders; Copyright © 1994 Elsevier.)

Milestones are characterized as belonging to several specific functional domains/streams, which usually include the following:

- Gross motor (skills involving the movement of the body or limbs as a whole)
- Fine motor (skills involving the manipulation of objects with the hands)
- Language and communication
- Cognitive and problem-solving
- Self-care (adaptive)
- Play
- Social

Each of these domains may be combined or subdivided in different ways to suit the clinical or scientific purpose for which they are being used (this is sometimes referred to informally as “lumping” or “splitting”). For example, language, communication, and social domains are often combined (“lumped”) into a larger communication/socialization domain for the purposes of emphasizing the broad range of skills important to social interactions (this is done to characterize one of the two large domains of dysfunction associated with autism spectrum disorder [ASD]; see Chapter 18). By contrast, language milestones may be subdivided (“split”) into expressive skills (spoken language), receptive skills (comprehension), and pragmatic skills (social/functional communication) for the purposes of carrying out a detailed analysis of a child’s language abilities. The way that specific domains are combined or subdivided is determined by the purpose for which

they are being used (examples of various clinical uses of milestones are shown in Table 11.2).

Clinical Usefulness

Developmental milestones are a necessary part of every aspect of clinical practice involving the assessment and management of children with potential or actual developmental challenges. But not all developmental milestones are weighted equally. Thousands of milestones have been described by a multitude of observers, but they vary significantly in practical utility. In general, the most useful milestones have the following characteristics:

1. They emerge in most children within a reasonably narrow and predictable range of ages.
2. They are easy to observe and describe.
3. They don’t vary tremendously in appearance from person to person.
4. They are functionally relevant.

Some milestones, such as a child taking her first independent steps, have all of these characteristics, whereas many others only have some of them. For example, in the fine-motor/adaptive domain of a well-known developmental screening test, a milestone referred to as the “thumb wiggle” is described (Frankenburg, Dodds, Archer, Shapiro, & Bresnick, 1992). A child is simply asked to wiggle her thumb after demonstration. Approximately 50% of children are able to do this by 39 months of age, and 90% are able to do it by 45 months of age. As a milestone, it emerges within a predictable range of ages, is easily observed and described, and is consistent in appearance. However, it could be argued that the

Table 11.2. Clinical uses of developmental milestones

Type of assessment	Purpose
Developmental surveillance	Monitoring and tracking of developmental progress
Developmental screening (with standardized screening instruments)	Identifying at-risk children for further evaluation
Diagnostic interview	Reviewing the history of developmental progress to establish the diagnosis of a developmental disability
Norm-referenced testing (with standardized instruments)	Comparing a child’s scores to reference populations (e.g., IQ, academic achievement tests)
Criteria-referenced testing (with standardized instruments)	Comparing a child’s progress against predetermined standards of performance (e.g., tests assessing reading progress based on established standards for grade level)

thumb wiggle has much less functional relevance than other motor milestones, such as walking and running.

By contrast, a milestone such as crawling, which has clear functional relevance, is notoriously variable in its presentation. Most children do some type of crawling toward the end of their first year, but the style of crawling can vary considerably, from belly (commando) crawling to crawling on hands and knees to “bear” crawling (walking on all fours). The emergence of these various forms of crawling occurs with considerable variability with respect to other, more predictable early motor milestones; in fact, some children skip crawling altogether. So, although crawling is considered an important early motor milestone, it has limited utility in determining whether a particular child has delayed motor development.

In clinical practice, developmental milestones also vary considerably in how they are observed and recorded. In many instances, caregivers (usually parents) are simply asked to report whether they have observed a behavior (milestone) at home—in other words, caregivers are used as proxy observers by the clinician. Milestones for language, social skills, and self-care skills are often elicited in this way. Other milestones are directly observed by the clinician, either passively or actively. For example, noting that a child walks into a room constitutes a passive observation of that skill. Other milestones are actively elicited, either by means of imitation (e.g., asking a child to hop on one foot after a clinician shows him how) or by providing a model (e.g., showing a child a picture of a circle and asking her to copy it). It is important to note that the method of observation may influence whether a child can demonstrate a particular skill. For example, a 2-year-old who may not be able to copy a circle from a picture may be able to imitate an adult drawing a circle.

Limitations and Misuses

In the hands of an experienced clinician, developmental milestones are essential tools that, when used correctly, yield critical information about a child’s developmental well-being. However, as with any tool, the characteristics and limitations of milestones must be understood to avoid being misused. In particular, milestones vary considerably in their level of precision. Developmental milestones are typically presented in the form of tables (see Table 11.3) demonstrating what skills emerge at what ages for different domains of development. These tables are typically derived from multiple sources, and the quality of evidence with regard to the precision of these milestones varies considerably (Dosman, Andrews, & Goulden, 2012).

In general, motor milestones and milestones for self-care skills tend to be more precisely defined and have a higher quality of evidence to support them than do milestones for language, social-emotional, and cognitive development. This is not to say that motor and self-care milestones are more important than other types of milestones; indeed, depending on the clinical circumstance, the other domains may and often do take precedence. It is therefore incumbent upon clinicians and early childhood educators to understand how and why they are using milestones and, in particular, what they are trying to accomplish when they encounter a child who may have a developmental concern.

DEVELOPMENT AND ADAPTATION: TRENDS AND KEY MILESTONES

Tables of developmental milestones (see Table 11.3) are necessary and useful, but in and of themselves they are not very effective at conveying a sense of the dynamism of the developmental process and its relation to real-world challenges. At its most basic level, development is fundamentally a process of adaptation, and developmental trajectories can best be understood with reference to the question, “What makes it possible for a child to develop into a fully functional adult?” To answer this question, one must consider how a child gradually adapts to both his/her physical and sociocultural environments.

Human beings are expert at adapting to change. This adaptability is a consequence of our evolutionary inheritance of bipedal locomotion (walking), tool use and advanced adaptive behaviors (problem-solving skills, especially those involving highly advanced fine-motor capabilities), our propensity for hypersocial behavior, and our capacity for symbolic thought and language.

It is useful to think of the processes of development as a kind of recapitulation of these evolutionary adaptations, and trends in development can be described accordingly in four broad categories: mobility (bipedalism), adaptive skills (tool use; manipulating the environment), hypersociality and theory of mind, and symbolic thought and language (Tuttle, 2017).

Mobility

Mobility refers to the ability of an organism to move in and successfully navigate a particular physical environment. The key developmental milestone for mobility in humans is independent walking, which first emerges for most children by 12 months of age. Early

Table 11.3. Developmental milestones*

Number of months/years	Domain						
	Gross motor	Fine motor	Self-help	Problem-solving	Social/emotional	Receptive language	Expressive language
Birth–1 month	Chin up in prone Turns head in supine Primitive reflexes evident	Hands fisted near face Palmar grasp reflex dominant	Sucks well	Follows face	Discriminates mother's voice Cries out in distress	Startles to voice/sound	Throaty noises
2 months	Chest up in prone Head bobs in sitting	Hands unfisted 50% Holds hands together Retains rattle placed in hand	Opens mouth at sight of breast or bottle	Reacts to visual threat Recognizes mother Follows large, high-contrast objects	Reciprocal smile Responds to adult voice and smile	Alerts to voice/sound	Coos Social smile (6 weeks) Vowel-like noises
4 months	Sits with trunk support No head lag when pulled to sit Props on wrists in prone Rolls front to back	Hands mostly open Reaches for objects Plays with rattle Clutches at clothes	Brings hands to mouth Briefly holds onto breast or bottle	Reaches for face, ring, rattle Follows object in circle Regards toys Mouths objects Shakes rattle Stares at new face longer	Expresses disgust Visually follows person across room Smiles at pleasurable sight/sound Stops crying to parent voice Reciprocal vocalizations	Regards speaker Orients toward voice Stops crying to soothing voice	Laughs out loud Vocalizes when talked to and when alone
6 months	Sits momentarily propped on hands Pivots in prone Bears weight on 1 hand in prone Rolls both ways Primitive reflexes minimally evident	Palmar grasp of cube (voluntary) Transfers objects between hands Rakes at small objects Reaches and grasps	Eats pureed baby food Feeds self crackers Places hands on bottle	Turns head to look for dropped spoon Regards small objects Touches reflection and vocalizes Removes cloth from face Bangs and shakes toys	Recognizes caregiver visually Forms attachment relationship with caregiver Stranger anxiety	Responds to name Stops to “no” Gestures for “up”	Says “ah-goo”; razzes, squeals (5 months) Reduplicative babbling with consonants (“bababa”) Reciprocal vocalizations with caregiver Smiles/vocalizes to mirror
7 months	Sits steadily without support Puts arms out to sides for balance Bounces on feet when held	Radial-palmar grasp (thumb-side of hand used for grasping)	Refuses excess food	Explores different aspects of toys Observes cube in each hand Finds partially hidden object	Looks from object to parent and back when wanting help	Looks toward familiar object when named Attends to music	Increasing variety of syllables

9 months	Pulls to stand Bear walks (on all fours)	Radial-digital (thumb-finger) grasp Bangs two cubes together Removes cube from cup, peg from pegboard	Holds own bottle Finger foods (bits of cereal) Bites, chews cookie	Seeks object after it falls silently to the floor Inspects, rings bell Pulls string attached to ring to obtain ring	Lets parents know when happy, upset Gaze monitoring (follows adult glance) Uses sounds to get attention Separation anxiety Follows a point ("Oh, look at . . .") Recognizes familiar people	Responds to "Come here" Looks for named family members Orients to name well Orients to bell	Says "dada" and "mama" (nonspecific) Nonreduplicative babbling ("dagaba") Imitates sounds Shakes head "no"
10 months	Cruises around furniture Creeps (crawls on hands and knees) Walks with 2 hands held	Isolates index finger and pokes	Drinks from cup held by caregiver	Uncovers a toy under cloth Pokes at pellet in bottle Tries to put cube in cup, but may not be able to let go	Experiences fear Looks preferentially when name is called	Enjoys peek-a-boo Waves "bye-bye" back	Says "dada" specific Waves "bye-bye"
12 months	Independent steps	Fine pincer (thumb-index finger) grasp Holds crayon, scribbles after demo Attempts 2-cube tower Stirs with spoon Throws objects	Finger feeds well Cooperates with dressing	Rattles spoon in cup Lifts box lid to find toy	Shows objects to parent to share interest Point to desired objects	Stops activity when told "no" Bounces to music Follows one-step command with gesture Looks toward 2 named objects	Says first words (other than "mama" or "dada") Points to desired objects Vocalizes to songs; uses gestures with vocalizations (e.g., waving, reaching)
15 months	Stoops to pick up toy; walks carrying toy Runs stiffly Climbs on furniture	Builds 3-cube tower Places 10 cubes in cup Imitates back-and-forth scribble Places round peg in pegboard	Uses spoons with some spilling Chews well Removes socks/shoes Attempts to brush hair	Dangles ring by string Reaches around clear barrier to obtain object Unwraps toy in cloth Dumps pellet out of bottle after demonstration Turns pages in book Places circle in single-shaped puzzle	Shows desire to please caregiver Solitary play Functional play; purposeful exploration of toys (trial and error) Points to objects to express interest Shows empathy Hugs back when hugged	Responds to 1-step commands without gesture Points to 1 body part Gets named object from another room on command Points out 1 named object out of 3	Uses 3–5 words Points to objects to express interest Vowel-like noises Jargon ("jibber-jabber") mixed with real words

(continued)

Table 11.3. (continued)

Number of months/years	Domain						
	Gross motor	Fine motor	Self-help	Problem-solving	Social/emotional	Receptive language	Expressive language
18 months	Runs well Throws ball Walks backward Creeps up and down stairs	Builds 4-cube tower Scribbles spontaneously Imitates vertical line (crudely)	Picks up and drinks from cup Removes some clothes Gets into adult chair Moves about house without adult	Dumps pellet from bottle spontaneously Places circle in a form board of 3 shapes Finds toy seen hidden under several layers Matches pairs of objects	Kisses touching lips to skin Periodically visually relocates caregiver Shows embarrassment, shame Shows possessiveness Pretend play with others (e.g., tea party)	Points to 2 of 3 named pictures; ² / ₃ objects Points to 3 body parts Points to self, understands "mine" Points to familiar people when named	Uses 10–25 words Uses "giant" words ("all gone," "gimme") Copies animal sounds Begins pointing to, naming pictures
24 months	Walks up and down stairs, both feet on each step, holding rail Kicks a ball Throws overhand	Builds single-line "train" of cubes Imitates vertical and horizontal line and circle Completes peg-board of round pegs	Uses spoon well; drinks well from cup; sucks through straw Gets undressed (no buttons); unzips; tries to put on shoes	Deduces location of familiar object Completes form board of 3 shapes (circle, square [20 months], triangle) Sorts objects Matches objects to pictures Shows use of familiar objects	Expresses thoughts about feelings Tea party with stuffed animals Kisses with pucker Watches other children intently; parallel play Shows defiance Begins to mask emotions for social etiquette	Points to 5–10 pictures; 5–6 body parts; 4 pieces of clothing Follows 2-step commands Understands me/you	Use 50+ words Two-word phrases (noun + verb) 50% intelligible Refers to self by name Can name several pictures
30 months	Jumps in place Walks up stairs, alternating feet, with rail	Builds 8-cube tower Builds "train" of cubes with stack Turns pages crudely Unscrews jar lid	Pulls pants up with help Verbalizes need for toilet Washes hands Brushes teeth with help	Matches shapes and colors Points to small details in pictures Replaces circle in reversed form board	Reduced separation anxiety Imitates adult activities (e.g., sweeping, talking on the phone)	Understands "just one" Follows 2 prepositional commands ("put block in/on box") Understands action words ("playing," "washing")	Uses 1st and 2nd person pronouns ("me," "I," "mine," "you"), phrases, partial sentences Names objects by use

3 years	Walks swinging arms opposite legs (synchronous gait) Walks up stairs, alternating feet, no rail Walks forward heel to toe Balances on 1 foot for 3 seconds Catches ball stiffly Pedals a tricycle	Copies circle Imitates 3-cube bridge Imitates cross-cuts with scissors crudely	Independent eating Puts on coat, shoes (no laces); unbuttons Toilet trained Pours liquids from one container to another	Draws 2- to 3-part person Understands long/short, big/small, more/less Knows own gender and age Matches letters, numbers	Some sharing Fears imaginary things Imaginative play Says what another person is thinking	Understands 3 prepositional commands Understands dirty, wet Points to objects by use Points to parts of pictures Understands negatives Groups objects (foods, toys)	Uses 200+ words Uses simple, grammatical sentences Uses pronouns correctly (including 3rd person) Gives first and last name Counts to 3 Begins to use past tense Uses plurals 75% intelligible Asks to be read to
4 years	Standing broad jump, 1 to 2 feet Gallops Catches bounced ball (4½ years) Balances on 1 foot for 4–8 seconds; hops on 1 foot 2 to 3 times	Copies square Imitates 3-cube gate Writes first part of name Ties a single knot	Uses fork well Goes to toilet alone; wipes after bowel movement Washes face and hands Brushes teeth alone Buttons	Draws 4- to 6-part person Can give amounts < 5 correctly Simple analogies (e.g., dad/boy: mom/?); ice/cold: fire/?; ceiling/up: floor/?) Points to letters/numbers when named Counts to 4 Recognizes common signs	Tells fibs, tries to trick others Has a preferred friend Labels happiness, sadness, fear, and anger in self Group play	Follows 3-step commands Points to things that are same vs. different Names things based on description (e.g., “You read it” -> book) Understands adjectives	Uses 300–1,000 words Tells stories, jokes Uses “feeling” words Uses past tense well Uses words about time 100% intelligible Can engage in back and forth conversation
5 years	Walks down stairs, alternating feet, with rail Skips Jumps backwards Balances on 1 foot for > 8 seconds; hops on 1 foot 15 times Running broad jump, 2–3 feet Walks backward heel to toe	Copies a triangle Cuts with scissors well Writes first name Builds stairs with cubes from model Puts paper clip on paper	Spreads with knife Independent dressing Bathes independently	Draws 8- to 10-part person Gives amounts < 10 Identifies coins Knows 10 colors Counts to 10 Knows letters and numbers well Knows sounds of consonants and short vowels by the end of kindergarten; reads 25 words	Has group of friends Apologizes Responds verbally to the good fortune of others	Knows right and left on self Points to different one in series Understands “er” endings (e.g., skater) Enjoys rhyming and alliteration Points correctly to side, middle, corner	Uses 2,000 words Retells stories with clear beginning, middle, and end Responds to “why” questions Repeats 6- to 8-word sentence Knows telephone number Defines simple words

(continued)

Table 11.3. (continued)

Number of months/years	Domain						
	Gross motor	Fine motor	Self-help	Problem-solving	Social/emotional	Receptive language	Expressive language
6 years	Tandem walks	Copies a diamond; flag Cuts with scissors well Writes first and last name; forms letters with down-going and counterclockwise strokes Builds stairs with cubes from memory	Ties shoes Combs hair Looks both ways at street Remembers to bring belongings	Draws 12- to 14-part person Number concepts to 20 Simple addition/subtraction Understands seasons Sounds out regularly spelled words Reads 250 words by the end of first grade	Has best friend of same sex Plays board games Distinguishes fantasy from reality Wants to be like friends, please them Enjoys school	Asks what unfamiliar words mean Can tell which words do not belong in a group	Uses 10,000 words Describes events in order Knows days of the week Repeats 8- to 10-word sentence Uses future tense

*Items in bold are key milestones referred to in the text.

OUR EVOLUTIONARY HERITAGE

Bipedal locomotion (upright walking) first emerged about 3 to 6 million years ago when prehuman hominins (human-like apes) branched off from the ancestral line that produced chimpanzees. The most famous example is the Australopithecine “Lucy,” who was essentially a bipedal chimpanzee adapted for life on the African savannah (away from the forest). She had a small body and a small brain but could walk on two legs.

The genus *Homo* (early humans) branched off from other hominins about 2.8 million years ago and developed more complex cooperative social structures and tool use to allow for a greater reliance on hunting and cooking. This allowed a change in gut anatomy and physiology (shorter intestines) and increased the caloric density of the diet to support larger bodies and, most importantly, larger brains. The rudiments of culture and language were likely present. *Homo erectus* was the first hominin to migrate extensively from Africa to Eurasia. Neanderthals evolved from a subgroup of these in Europe, and Denisovans evolved in central Asia.

Homo sapiens (modern humans) emerged in Africa about 200,000 to 300,000 years ago during a period of significant climate change, which pushed our species toward increased adaptability. Modern humans evolved to be experts at adapting to change by becoming hypersocial beings who could anticipate thoughts and intentions of others (theory of mind) and who could think symbolically (a primary manifestation being the emergence of language; Tuttle, 2017).

gross motor development subserves the emergence of this key ability.

At birth, movement patterns are dominated by **primitive reflexes** (Accardo, 2008). These are “programmed” motor responses that are present at birth, such as the ability to orient toward and suckle a nipple. They gradually fade during the first year and are replaced by voluntary motor responses, except in children with cerebral palsy, in which case the pathological persistence of primitive reflexes may be observed (see Chapter 21).

By 7 months of age, most children have developed enough head and trunk control that they are able to maintain a sitting position on their own. They have also developed a number of **automatic movement reactions**, or protective responses, such as propping their arms forward or to the side to catch themselves if they begin to tip over. A parallel development during these early months is the emergence of floor mobility skills, such as belly (“commando”) crawling and rolling over, which culminate in creeping (crawling on knees and extended arms) by the end of the first year. The trend toward floor, or “horizontal,” mobility is quickly overcome in most children by an increasing emphasis on “vertical” mobility. By 9 months of age, most children can pull up to a standing position while holding on to furniture, and by 10 months they can walk holding on to furniture (also called “cruising”). Most children take their first independent steps by about 12 months of age.

The further development of mobility-related skills during the toddler and preschool years can be characterized as an elaboration of skills in five categories: standing and balancing, walking, running and jumping, climbing, and general coordination (Gerber, Wilks, & Erdie-Lalena, 2010).

Standing and Balancing By about 14 months of age, most children can stand up without holding on to anything, and by 15 months, they can stoop down to pick up a toy. By their second birthday, most children can easily squat down and stand back up at will, and they usually do so multiple times in a typical day. By 30 months of age, they can stand on a balance beam without falling off. By 3 years of age, most children can balance on one foot for 3 seconds or more, and by their fourth birthday they can hop on one foot two or three times. By 5 years of age, they can typically balance on one foot for more than 8 seconds and can hop on one foot 15 times.

Walking When children start walking at 12 months of age, they are of course a bit unsteady, but most children are walking well by 15 months of age and can also carry a toy while they walk. Most children can walk backwards by 18 months of age. Between 2½ and 3 years of age, most children develop the adult pattern of walking with their arms swinging opposite of their legs, referred to as **synchronous gait**. By 3 years of age, most children can walk heel-to-toe forward, and by 5 years of age, they can do this backward.

Running and Jumping Some children seem to start running as soon as they have learned to walk, but most can at least run stiffly by 15 months of age and can run well by 18 months. Most children can jump in place by 30 months of age and can make a standing broad jump 1 to 2 feet by 4 years of age. By 4 years of age most children can also “gallop,” which is an honest but awkward attempt at skipping, and they can actually skip (as well as make a running broad jump) by 5 years of age.

Climbing By 15 months of age, most children can climb on furniture, and by 18 months they can crawl (creep) up and down stairs. By 24 months, they can usually walk up and down stairs, stopping with both feet on each step, while holding onto a rail. By 3 years, most children can walk upstairs using alternating feet, and they can even do this without holding onto a rail; by 5 years they can descend the stairs with alternating feet, but it may still take a few years before they can do so without holding on to a rail.

General Coordination General coordination refers to gross motor skills that especially involve coordination of the legs and arms together and require complex motor planning, timing, and balance. This discussion will focus on ball-handling skills and learning to ride a bicycle. Most children can first throw objects with clear intent by about 12 months of age and can first throw a ball stiffly by 18 months of age. By 24 months most children can throw a ball overhand and kick a ball. Most children can catch a ball with their arms stiffly extended by 3 years of age, can catch a bounced ball by 4½ years of age, and many children can play at least a rudimentary game of catch by 5 to 6 years of age.

Most children can pedal a tricycle by 3 years of age (the motion of pedaling is similar to the motion of climbing stairs with alternating feet, which also emerges at this age). Ages at which children learn to ride a bicycle tend to be extremely variable, and for that reason are often not included in charts of developmental milestones. In general, many children can learn to ride a bike with training wheels by kindergarten, but it can take years before a child can ride a bike without training wheels, although many have accomplished this by the time they have entered second grade.

Adaptive Skills

For the purposes of this discussion, **adaptive skills** refer to the broad range of abilities that allow human beings to manipulate their environment. This includes the literal manipulation of the environment with the hands through the application of fine-motor skills and the abstract manipulation of the environment by means of a variety of cognitive and problem-solving abilities (Gerber et al., 2010; Wilks, Gerber, & Erdie-Lalena, 2010).

Early Fine Motor Skills The first year of life is marked by the development of basic fine motor skills, and a key milestone is the development of the **pincer grasp** (the ability to pick up a small object between the tips of the thumb and index finger) by 12 months of age.

At birth, the hands are dominated by a primitive reflex called the **palmar grasp reflex**. Newborns automatically grab any object that comes into contact with the palm of the hand. By 4 months, this reflex has faded, and the child begins to grasp objects voluntarily. By 6 months, most infants can use a palmar grasp (using the fingers and thumb as a unit, like a mitten) to reach for and pick up objects like a 1-inch cube, but they have trouble picking up smaller objects, like a bit of cereal. At this age children can also transfer objects between hands. By 7 months of age, most infants tend to use the thumb and first few fingers of the hand (**radial-palmar grasp**) to pick up objects rather than using the whole hand. By 9 months, the fingers are able to operate independent of each other (like a glove), such that an object can be grasped between the thumb and the side of the first finger (**radial-digital grasp**). The grasp pattern matures into the **pincer grasp** described above by the first birthday.

Later Fine Motor Skills As early as 9 months of age, infants begin to experiment with the properties of objects that they have learned to grasp (for example, banging two cubes together). By 12 months, infants usually begin to use objects as a means to an end (trying to scribble with a crayon or trying to stack one block on another); in other words, shortly after 1 year of age, most children have learned how to use objects as tools. Although any object that comes within a young child's reach is subject to experimentation, it is customary to describe the progression of skills with representative and commonly available objects: cubes and cups, crayons, pegboards, puzzles, and scissors.

Cubes and Cups, Pegboards, and Puzzles Most infants can retrieve a cube from a cup by 8 months of age, but they cannot usually release a cube into a cup voluntarily until after 10 months. By 15 months, they can fill a cup with cubes and drop things on the floor from a highchair; in fact, many 1-year-olds make this into a game, and they relish enticing their caregivers to repeatedly retrieve the dropped objects, only to be dropped again (this game is sometimes called casting).

Once a child can control the release of an object more precisely, he can then move on to more advanced skills, such as stacking. By 15 months of age, most children can build a two- to three-cube tower; they can also release a small pellet into a bottle. Between 2½ and 3 years of age, children generally have developed sufficient dexterity to be able to construct a tower of 10 cubes. During the preschool years children develop increasing sophistication in their ability to create more complex forms with blocks that reflect increasing dexterity and problem-solving abilities (Figure 11.2).

Figure 11.2. Fine motor skills: cubes and shapes. Figures illustrate the progression of fine motor skills as demonstrated by the ability of a child to construct with cubes and drawings. (Key: *Spont.*, produced spontaneously; *Imit.*, produced by imitation after demonstration by an adult; *Copy*, copied from a model; *Mem.*, produced from memory of a model; data from Gerber et al., 2010.)

Pegboards are often used in developmental testing and are a relatively pure measure of dexterity in contrast to other fine motor tasks that make greater cognitive demands. Infants can first remove a round peg from a pegboard at the same age that they can first remove a cube from a cup (8 months). By 15 months, they can place a single round peg in a pegboard and complete a pegboard with round pegs well before their second birthday.

Compared with pegboards, puzzles make relatively greater demands on visual-spatial reasoning and cognition. Most 18 month olds can place a circle shape into a puzzle consisting of a circle, square, and triangle, and they can usually complete the puzzle by 24 months (although 2-year-olds get confused if you flip the puzzle over so the shapes change position).

Crayons and Scissors Children start experimenting with crayons by making marks or scribbles on paper (or walls, if paper is not available) as early as 12 to 15 months. By 24 months, they can imitate producing vertical and horizontal lines and approximations of circles after demonstration. By 3 years of age, most children can draw a circle from a copy without needing its production demonstrated, and the ability to produce more difficult shapes follows (see Figure 11.2). By this age, most children are also able to draw a person with

two or three parts. By 6 years of age, most children can draw a much more detailed picture of a person with more than a dozen parts.

The ability to use scissors along with the ability to draw simple shapes are among the skills often included in lists of kindergarten readiness. Most children are first able to operate scissors awkwardly by 3 years of age, but they can usually use them well by their fifth birthday.

Problem-Solving: Memory and Object Permanence

Relatively few fine motor skills are pure manifestations of motor dexterity; most require cognitive and problem-solving abilities to a greater or lesser extent. Indeed, the ability to manipulate the environment mentally far exceeds the limits of human physical dexterity and pervades every aspect of adult functioning.

Fundamental to these cognitive abilities is the capacity to remember, register, record, and retain mental traces or images of the world. Humans are not born with this ability fully formed. Prior to 6 months of age, infants seem to live purely “in the moment.” If something (or someone) is not immediately available to their senses, they no longer exist as far as the infant is concerned (this is the ultimate example of the expression “out of sight, out of mind”). It is thought that very

young infants lack the ability to form a stable mental image of the things in their world.

Their ability changes as early as 7 months of age, when infants begin to look for objects that are partially hidden, suggesting that they are forming a mental image of something that is only partially visible. By 11 months, they are able to retrieve objects completely hidden under a cloth or cup as they have retained the image. This early ability to create and sustain a stable mental image of objects is called **object permanence**. This is fundamental to memory and is necessary to the development of all subsequent cognitive skills. It is also critical to one's emotional and social life. It is no coincidence that **stranger anxiety** (unease in the presence of strangers) emerging at 6 months and **separation anxiety** (fear at losing sight of a caregiver) emerging at 9 months arise at the same time as object permanence. Both milestones rely on the child's ability to form a stable mental image of the caregiver to draw on when faced with a stranger or the absence of that caregiver. Object permanence is also necessary to the development of the **theory of mind**, a critical aspect of social cognition (see below).

Problem-Solving: Self-Care Skills A prominent and practical manifestation of burgeoning problem-solving skills in early childhood is the acquisition of self-care skills. Skills in this domain also draw heavily on other functional domains, including basic fine and gross motor function, and occur in specific social contexts. Whether a child learns to eat with a spoon or with chopsticks, what types of clothes a child will wear, and expectations for hygiene and toileting are culturally determined.

Drinking and Eating As early as 6 months of age, most infants are able to feed themselves easy-to-grasp finger foods, such as crackers, and by 12 months of age, they are starting to be able to drink from a cup. By 12 to 15 months, a mature chewing pattern has also emerged such that children are safely able to manage a wider variety of food textures. By 15 months, most children can use a spoon awkwardly to feed themselves, and by their second birthday, can use both a spoon and a cup well; most children are also able to drink through a straw at this stage. By 3 years of age, most children can feed themselves an entire meal. By 4 years of age, most children can use a fork well, and by 5 years they can spread with a butter knife.

Dressing Between 6 and 12 months, infants learn to cooperate with getting dressed, and by 15 months, most have figured out how to remove their shoes and socks. By 18 months, they can typically take off other clothing

items, and by 24 months most can get undressed on their own (unless buttons slow them down; they can usually unzip zippers, though). By 3 years, they can get dressed with help, and by 4 years they can manage buttons on their own. By 5 years of age, most children can completely dress themselves except for tying their shoes, which in an age of Velcro and slip-on shoes is often learned much later.

Hygiene and Toileting Children are typically dependent on caregivers for hygiene and toileting needs until their second birthday, although many will experiment with combs and brushes and fuss when they need a diaper change by 18 months of age. By 30 months most children can wash their hands and brush their own teeth with assistance. Most will have started the process of toilet training, although the onset and completion of this task is extremely variable. By 4 years of age, most children are toilet trained, can go to the toilet on their own, and can wipe themselves after a bowel movement. At this age, most children can also wash their face and hands and brush their teeth without help. By 5 years of age, most children can dress and bath independently, and by 6 years, most can comb and brush their own hair without help.

Problem-Solving: Preacademic Skills For the purposes of this discussion, preacademic skills refer to knowledge about colors, shapes, letters, numbers, books, and words that provide the foundation for kindergarten (i.e., kindergarten-readiness skills). The ability to match and sort objects and to recognize and categorize pictures forms the basis for these skills. As previously discussed, by 12 months of age most children have begun to use objects with a purpose in mind, and it is also at this age that children begin to show an interest in looking at pictures in books.

By 15 months, children begin to play with shape puzzles, and they become familiar with how to turn the pages of a book. By 18 months, children can typically match pairs of objects, and by 24 months they can sort objects and match objects to pictures. By 30 months, these matching skills have been extended to colors and shapes, as well as to letters and numbers by 3 years of age. By 4 years of age, most children have learned to identify common colors and shapes by pointing to them and can also point out some letters and numbers. Most can count to four by rote and are beginning to be able to identify quantities.

By 5 years of age, most children can name all of the letters and numbers, can name 10 colors, have learned the sounds of the consonants and short vowels, and may recognize a few words. They can count to 10 by

rote and identify amounts up to 10 as well. By 5 years most children can also write their first name. By the end of kindergarten, most children can read 25 words, and by the end of first grade, most children can sound out words well, read 250 words, write their first and last names, and perform simple addition and subtraction.

Hypersociality and Theory of Mind

Humans are intensely social beings, and, along with language use, this hypersociality is a hallmark of our species. The social brain hypothesis (Dunbar, 2009) proposes that the cognitive requirements of functioning in large social groups was the crucial factor in driving the evolution of larger brains, greater intelligence, and the emergence of symbolic thought and language in our species. Stated differently, the ability of human beings to anticipate the thoughts and intentions of others and to grapple with the complexities of interpersonal relationships made our species smarter and made it possible for us to survive in and adapt to an unpredictable world.

The ability to understand something about the thoughts and intentions of others—to perceive the world from their perspective—is referred to as **theory of mind** (von dem Hagen, Stoyanova, Rowe, Baron-Cohen, & Calder, 2014). Theory of mind is fundamental to social cognition and human social interactions and, when lacking, results in one of the most significant developmental disabilities, ASD (see Chapter 18).

Some of the rudiments of theory of mind are evident even in early infancy. Infants are born recognizing their mothers' voices, and by 2 months of age they can recognize familiar faces and demonstrate a reciprocal social smile. By 4 months, this reciprocity extends to back-and-forth vocalizations, and by 6 months a clear attachment to the primary caregiver is evident. With the advent of object permanence (see previous discussion), 6 month olds can also maintain a stable mental image of their primary caregiver, and this, along with the attachment that has formed, leads to the emergence of stranger and separation anxiety (Gerber, Wilks, & Erdie-Lalena, 2011).

By 8 months of age, children demonstrate **gaze monitoring**. A child notices that her mother is looking at something across the room, and she follows her mother's glance to see what she is looking at. This simple act suggests something profound—that the child is seeing that room from her mother's perspective. In other words, the child is exhibiting **perspective-taking**, a fundamental component of theory of mind. By 9 months, children can similarly track where someone is pointing, and by 12 months children begin to use pointing themselves as a means of indicating wants

and needs (this is referred to as **proto-imperative pointing**). Children typically engage their parents with eye contact, look toward the desired object, point to the desired object, and then look back at the parent while continuing to point. This suggests reciprocity in perspective-taking; the child perceives his/her parent's point of view and then uses pointing, eye contact, and vocalizations to influence the parent to see things from the child's perspective and respond accordingly. By 15 months of age, the child will also point to objects simply to express interest or share an experience, as if to say, "See what I'm looking at, I want you to look, too." This is referred to as **proto-declarative pointing**.

By 18 months of age, children demonstrate embarrassment and shame, as well as empathy, all of which presuppose an awareness of the perceptions and emotional states of others in the social environment. It is also at this age that the capacity for **pretend play** (e.g., having a "tea party") emerges. Pretend play, even when done alone, has at its heart the idea of intentionality and agency (acting to produce a particular result) learned through social interaction and applied to the world of things. When a child plays with a stuffed animal or doll, he is imputing the qualities of mind, feeling, and agency to that toy.

Between 18 and 24 months, children develop an increasing sense of autonomy, and they begin to exhibit defiant behavior in an attempt to establish the priority of their own intentions and desires above those of their caregivers. Two-year-olds exhibit the ability to **parallel play** (playing in the company of other children); by 3 years, they are able to engage in **cooperative play** (involving sharing, turn taking, and common goals). Three-year-olds have a vivid imagination, and they are able to engage in true **imaginative play**, which includes the ability to imagine that a thing is something other than itself (e.g., that a stick is a magic wand). It is also at this age that children develop fears of imaginary creatures. Four-year-olds are able to use this capacity to imagine things being "other than they actually are," to tell fibs, or to try to "trick" others by saying something they know to be untrue in order to get a reaction.

Four-year-olds are also able to pass the "ultimate" test of theory of mind, the false belief test (Bauminger-Zviely, 2013). This is also called the **Sally-Ann Test**, after the original version of the test (Baron-Cohen, Leslie, & Frith, 1985). The child being tested is presented with the follow scenario:

Sally and Ann are together in a room; Sally has a basket. Ann has a box. Sally puts a marble in the basket and leaves the room. While Sally is gone, Ann moves the marble to the box. When Sally comes back, where will she look for her marble?

A 3-year-old presented with this puzzle believes that Sally will look in the box because the 3-year-old knows it's there, but a typical 4-year-old will realize that, from Sally's perspective, the marble should still be where she left it.

The continued development of theory of mind and the nuances of perspective-taking are at the basis of ongoing emotional development throughout the life span. It provides the foundation for friendship and also serves as the basis for the development of a mature morality based on an appreciation of the interests and needs of others (Killen & Smetana, 2013). It also helps to explain people's interest in gossip and the contemporary obsession with social media; this propensity seems to be built into one's DNA and hardwired into the brain.

Symbolic Thought and Language

Since the advent of the Internet, humans are inundated with words and language in its myriad forms and are liable to think of its written manifestations when we hear the word "language." But written language is a relatively recent invention, and language is fundamentally a social and verbal phenomenon with a biological origin. The fact that language has a basis in biology is supported by the observation that children seem to be "programmed" for language learning and typically become fluent in their native language through simple social exposure to its use without any formal instruction. Infants also show a sensitive period in early infancy, during which time their auditory system is able to process any phoneme of any language. After about 9 months of age, children become preferentially sensitive to the phonemes of their native language. And as noted previously, language has a firm basis in our hypersocial nature. Through reciprocal gestures, facial expressions, and vocalizations, infants establish the basis for communication well before their first birthday and well before they can use spoken language.

When children do begin to speak, their first words are usually "mama" and "dada" (if the spoken language is English). They begin to use other words by 12 months of age, but it is clear that they can understand words such as "no" and the names of family members well before they can speak. Between 12 and 18 months of age, children gradually acquire the ability to use other single words and can typically say about 10 to 25 words by 18 months. Up to this point, children tend to enjoy using words to label objects and pictures, and to a limited degree they use words to indicate wants and needs. They, however, are still reliant on gestures, facial expressions, and nonspecific vocalizations to make their needs known.

Typically beginning between 18 and 24 months, children undergo a radical expansion and transformation of their language skills. By 24 months, children are using a minimum of 50 words. More importantly, they are beginning to combine words into phrases, and eventually sentences, using the grammar of their native language. Initially phrases are dominated by simple nouns and verbs, but by 30 months other parts of speech, such as pronouns, come into use. By 3 years of age, most children can use complete, grammatical sentences that are intelligible most of the time, and they can say more than 200 individual words. By 4 years of age, children are using as many as 1,000 words, and they can tell simple stories and jokes, use the past tense, and engage in reciprocal (back-and-forth) conversation. By 5 years of age children can use the future tense, complex sentence forms, and can retell complicated stories with a clear beginning, middle, and end (see Chapter 17 for a detailed discussion of speech, language, and communication).

DISTINGUISHING TYPICAL AND ATYPICAL DEVELOPMENT

Isabella, the 2-year-old described in the case study at the beginning of this chapter, presented with a very common developmental concern, a delay in the development of her speech and language skills. The term "delay" figures prominently in discussions of developmental problems, and in this case recognizes that Isabella is not doing something (talking) that we would expect a child her age would do. **Developmental delays** may refer to the late emergence of a particular skill or milestone or the general slowing of development within or across broader domains of development. Development that is more delayed in some domains than others is referred to as a **dissociated** pattern of delay. Development that is significantly delayed across all domains is referred to as a **global developmental delay**.

Development can also deviate or diverge from typical patterns of development. Whereas a child with delays exhibits typical milestones at later-than-expected ages, a child with divergent traits exhibits qualitatively different skills or behaviors that are not usually seen in most children at any point during their development. For example, children with ASD (see Chapter 18) exhibit a variety of divergent behaviors such as echolalia (randomly repeating bits of favorite TV shows or conversation) or unusual, repetitive body movements, such as hand flapping. Depending on the nature of the developmental problem, children will exhibit variable degrees of delay and divergence, and it is the task of the developmental practitioner to

recognize, identify, and characterize the nature of these changes (Accardo, 2008; Voigt, 2018; see Chapter 12 for a detailed discussion of the use of these concepts in the diagnostic process).

Recognizing Problems: Developmental Surveillance

Isabella's speech difficulties first came to light when her pediatrician asked her mother about developmental milestones as part of a well-child visit. Her pediatrician was knowledgeable about typical development and routinely inquired about specific milestones at each well-child visit. As part of her training, she learned to use charts and tables of developmental milestones as references for typical development, and she incorporated this information into the questions that she asked parents about their children.

The process of review of developmental progress over time is known as **developmental surveillance**. Primary care providers, including pediatricians, family practitioners, nurse practitioners, and physician assistants, are uniquely positioned to provide such surveillance due to their frequent contact with young children throughout the critical early stages of their development. Optimizing the parent-practitioner partnership is critical to ensuring the success of developmental surveillance as parents are the primary source of the information that forms the basis for surveillance (see Box 11.1).

Developmental surveillance provides the foundation and context for all other processes of developmental assessment, but it has its pitfalls. Clinicians vary considerably with regard to their level of experience and expertise in identifying developmental differences. Variability also exists in the degree to which individual clinicians prioritize developmental issues relative to the many other concerns that are addressed during a typical well-child visit. Some clinicians utilize

up-to-date developmental references and surveillance tools, whereas others may rely on their memory of potentially out-of-date information from early in their training. Studies indicate that as a consequence of this variability, many children with potentially significant developmental concerns may not be identified for early intervention services (Thomas, Cotton, Pan, & Ratliff-Schaub, 2012). Surveillance is therefore considered a necessary, but not entirely sufficient, part of the process of identifying delayed and divergent development.

Recognizing Problems: Developmental Screening

In addition to asking Isabella's mother about her development, her pediatrician also administered a standardized screening test. In 2006, the American Academy of Pediatrics (AAP), recognizing the limitations of developmental surveillance, published guidelines recommending that all children routinely undergo developmental screening using a standardized screening tool (test) at 9, 18, and 30 months of age (see Box 11.2). In addition, the screening tool should be used at any visit when surveillance suggests a developmental problem (Council on Children with Disabilities, 2006).

Several commonly used developmental screening tests are described in Table 11.4. The original recommendations were subsequently modified to allow screening at 24 months as an alternative to 30-month testing, mainly because most primary care offices do not see children for well-child visits at 30 months (visits are keyed to vaccination schedules; Marks & LaRosa, 2012).

Isabella's pediatrician decided to administer a screening test both because of the child's age and because of concerns about speech identified through surveillance. **Screening tests** are primarily designed to distinguish children who are at risk for developmental problems from those who are not, and, as such, they usually yield a "pass" or "fail" result. Depending on

BOX 11.1 INTERDISCIPLINARY CARE

The Parent-Practitioner Partnership in Recognizing Development Delay

Because they have regular contact with children during the early, critical stages of development, medical practitioners (pediatricians, family practice physicians, pediatric nurse practitioners, and physician assistants) have a mandate to identify developmental problems and refer children for early intervention. This goal can only be accomplished in close partnership with parents and other primary care givers, whose knowledge of and concerns about their children form the basis for developmental surveillance and screening. Indeed, it is typically parents who first recognize problems in their children, and the wise practitioner will take these concerns seriously and act promptly. A "wait-and-see" approach to development delay is almost never advisable.

BOX 11.2 EVIDENCE-BASED PRACTICE**Implementing Recommendations for Developmental Screening**

The American Academy of Pediatrics (AAP)'s 2006 guidelines for developmental screening and surveillance recommended automatic administration of a validated screening tool for all children at ages 9, 18, and 24 or 30 months (Council on Children with Disabilities, 2006). A survey of pediatricians completed in 2009 revealed that although the recommendations did result in a significant increase in screening, more than one half of practitioners were still not following the AAP guidelines (Radecki, Sand-Loud, O'Connor, Sharp, & Olson, 2011).

In response to this, the New Mexico Developmental Screening Initiative was created (Malik, Booker, Brown, McClain, & McGrath, 2014). Seven large practices in a large urban area were involved in an intensive quality improvement project to improve rates of developmental screening. After 1 year, rates of screening in these practices improved from 27% to 92%.

the test, a "fail" result should prompt either follow-up screening procedures or referral for diagnostic assessment and potential services.

Many screening tests utilize specific developmental milestones in the assessment process, but the

limitations of individual milestones are overcome by incorporation of multiple milestones into the process of standardization of the test as a whole. Other screening tests, such as the one that Isabella's pediatrician used, rely instead on caregiver report of concern about

Table 11.4. Commonly used developmental screening tools

Screening tool	Characteristics	Administration and uses	Interpretation
Ages and Stages Questionnaires®, Third Edition (ASQ®-3; Squires, Bricker, & Potter, 2009)	0–60 months Sensitivity 70%–90%; Specificity 76%–91% Based on specific milestones by age	Self-administered (parent) with or without clinician assistance 30 items 10–15 minutes Used as first-line screening tool for general developmental concerns and to aid surveillance	Yields pass or fail results for domains and recommendations for referral
Modified Checklist for Autism in Toddlers, Revised (M-CHAT-R; Robins et al., 2014)	16–30 months Based on specific questions regarding communication and socialization skills	Self-administered (parent) 20 items 5–10 minutes	Yields scores: high risk (8–20; referral for EI), medium risk (3–7; rescreen with M-CHAT-R/F), low risk (0–2; reassurance)
Modified Checklist for Autism in Toddlers, Revised with Follow-up (M-CHAT-R/F; Robins et al., 2014)	16–30 months Based on specific questions regarding communication and socialization skills	Interview by clinician 5–10 minutes Used to rescreen medium risk scores from M-CHAT-R	Scores 2 or greater indicated referral; other rescreen at future visits
Parents' Evaluation of Developmental Status (PEDS; Glascoe, 2007)	0–9 years Sensitivity 74%–79%; Specificity 70%–80% Based on parental concern Available in 14 languages	0–9 years Sensitivity 74%–79%; Specificity 70%–80% Based on parental concern Available in 14 languages	Scores fall into categories (decision pathways) (high risk = referral; moderate risk = further screening or referral; low risk = education and reassurance)
Parents' Evaluation of Developmental Status—Developmental Milestones (PEDS-DM; Brothers, Glascoe, & Robertshaw, 2008)	0–8 years Sensitivity 70% or greater; Specificity 77%–93% Based on specific milestones by age	Administered by clinician 6–8 items 4–10 minutes Used to supplement PEDS, to rescreen moderate risk PEDS, and to aid surveillance	Yields pass or fail results Interpretation made in conjunction with other screening tools (such as the PEDS)

Sensitivity refers to the percentage of children with true delays correctly identified. *Specificity* refers to the percentage of children without delays correctly identified. Developmental screening tests should have sensitivities and specificities > 70%.

development, and they are based on research recognizing that parents/caregivers reliably identify developmental problems in their children (Glascoe & Marks, 2011). An effective screening test is simple and fast to administer, and it can identify children with developmental problems (the test has good sensitivity) as well as children who do *not* have developmental problems (the test has good specificity).

Because of increasing concerns about identifying children with ASD, the AAP has also recommended that autism-specific screening tests be administered to all children at 18 and 24 months of age (Zwaigenbaum et al., 2015).

Early Intervention

The primary purpose of developmental surveillance and screening is to identify children for referral to early intervention. Multiple studies have identified the importance of providing early intervention in optimizing long-term developmental outcomes in children at risk for or manifesting developmental disabilities (Wallander et al., 2014). **Early intervention** refers to a specific, federally mandated program for children from birth to 3 years of age (see Chapter 31), but it more broadly refers to a variety of special education services and therapeutic interventions that are employed throughout early childhood.

Developmental Diagnosis

Developmental surveillance and screening are critical to identifying children with atypical development, but they do not, in and of themselves, diagnose the nature of these problems. The diagnostic process, which involves a complex consideration of a child's developmental history combined with the results of screening and testing procedures, is discussed in detail in Chapter 12.

SUMMARY

- The term *development* refers to the characteristic, predictable ways that behavior changes during the human life cycle and can be characterized in terms of specific functional domains.
- The term *typical* is preferred to the term *normal* when describing developmental change as experienced by most children.
- A variety of developmental theories have been developed in an attempt to describe and explain the complexities of child development.
- Developmental milestones are used to map the processes of developmental change, and while they are indispensable in clinical practice, they must be understood and used carefully to avoid misuse and misinterpretation.
- It is useful to think of the processes of development as a kind of recapitulation of the evolutionary adaptations of our species.
- Trends in development can be described in four broad categories: mobility (bipedalism), adaptive skills (tool use; manipulating the environment), theory of mind (hypersociality), and language (symbolic thought).
- Atypical development occurs when a child exhibits delays or otherwise diverges from expected developmental trajectories, either in some domains more than others (dissociated development) or across all domains of function (globally impaired development).
- Clinicians, and primary care providers in particular, have a mandate to identify children with atypical development through the processes of developmental surveillance and screening.
- The use of standardized screening tools is recommended at 9, 18, and 24 or 30 months or when concerns arise about a child's development at any age.

CHAPTER 12

Diagnosing Developmental Disabilities

Scott M. Myers

Upon completion of this chapter, the reader will

- Recognize the major streams/domains of development and their role in defining the spectrum and continuum of developmental disabilities
- Understand atypical patterns of development including delay, dissociation, deviance, and regression and their role in developmental diagnosis
- Discover the components of the developmental diagnostic evaluation and how they contribute to the diagnostic formulation

Children typically present for developmental diagnostic evaluation because of concerns about not attaining cognitive, motor, or social/adaptive milestones or about the presence of aberrant behaviors. These issues may be raised spontaneously by parents or other caregivers or teachers, or they may be elicited by health care providers through developmental surveillance and screening (American Academy of Pediatrics et al., 2006; Bellman, Byrne, & Sege, 2013). The diagnostic process enables the clinician to begin to answer the four fundamental questions that most parents have when they seek evaluation:

1. What is wrong with my child? (Diagnosis)
2. What is going to happen to my child over time? (Natural history/prognosis)
3. What can be done to improve my child's condition? (Treatment)
4. What caused my child's condition? (Etiology)

In this chapter, general principles and processes involved in diagnosis of developmental disabilities are reviewed. Details about each of the specific disabilities and procedures, such as developmental or psychological testing, are available in other chapters in this volume (Chapters 11 and 13) and in other current textbooks in the field (e.g., Accardo, 2008; Augustyn, Zuckerman, & Caronna, 2011; Carey, Crocker, Coleman, Elias, & Feldman, 2009; Sonksen, 2016; Voigt, Macias, Myers, & Tapia, 2018; Wolraich, Drotar, Dworkin, & Perrin, 2008). The focus is on developmental disabilities caused by brain dysfunction rather than those caused by sensory deficits (e.g., blindness or deafness); orthopedic impairments; or disorders of the spinal cord, peripheral nervous system, or muscle.

■ ■ ■ CASE STUDY

At her 18-month routine health supervision visit, Julia's parents raised concerns about delays in her attainment of

developmental milestones and lack of intelligible speech. These concerns were validated by a parent-completed general developmental screening measure, and her pediatrician confirmed the concerns and noted that her head circumference measurement was at the 98th percentile for age. She was referred to the local early intervention program for evaluation, which confirmed delays in cognitive, communication, social-emotional, adaptive, and physical development. Speech-language therapy, occupational therapy, and physical therapy were initiated. Audiological assessment was completed, and her hearing was found to be normal. Because of the macrocephaly (large head size) and developmental delays, magnetic resonance imaging of Julia's brain was completed. The results were normal.

Speech development progressed more slowly than other aspects of development, and Julia developed some repetitive behaviors and other features that raised concerns about the possibility of autism, prompting referral for additional evaluation. Neurodevelopmental assessment at age 3.5 years revealed global developmental delay (GDD), including delays of approximately 35% in receptive language and nonverbal problem-solving abilities and approximately 60% in expressive language. General adaptive functioning was also significantly subaverage. Speech intelligibility was very poor, and she had difficulty imitating words. However, although she exhibited some features commonly associated with autism, Julia did not meet criteria for autism spectrum disorder (ASD). Her height and weight were both at approximately the 40th percentile, her body mass index was just above the 50th percentile, and her head circumference was at the 98th percentile. No dysmorphic features or structural anomalies were noted. Neurologic examination was notable for mild neuromotor abnormalities, including mild hypotonia; mixed or unclear hand dominance; and qualitatively immature coordination. Chromosomal microarray analysis (CMA; see Chapter 1) was recommended to try to determine the etiology of Julia's GDD, superimposed expressive language disorder (suspected to be a motor speech disorder), macrocephaly, and mild neuromotor abnormalities; she was referred to a pediatric speech-language pathologist with expertise in the diagnosis and treatment of motor speech disorders in young children.

The speech-language pathologist determined that Julia met criteria for childhood apraxia of speech. As such, he increased the intensity of therapy, focusing on improving functional communication through the use of sign language and gestures, while building on sounds in her phonemic repertoire to increase verbal output. Chromosomal microarray analysis revealed an almost 600-kb deletion on the short arm of chromosome 16 at 16p11.2,

consistent with a molecular diagnosis of 16p11.2 recurrent deletion syndrome, which explained her developmental diagnoses. The test results and implications were explained to her parents with the help of a genetic counselor, and they were relieved to learn that neither of them had the deletion, meaning that this was a *de novo* (new) deletion in Julia; as such, the chance that their subsequent children would have 16p11.2 recurrent deletion syndrome was estimated to be less than 1%. Radiographs of the spine ruled out vertebral anomalies and scoliosis, which occur in about 20% of individuals with this deletion, and her parents were counseled about the increased risk of obesity and, less commonly, seizures. Her family became active in a support group and found it very helpful to meet other children and families affected by 16p11.2 recurrent deletion syndrome. When Julia was 5 years old, the diagnosis of GDD was replaced by the diagnosis of mild intellectual disability (ID), based on the results of psychological testing.

Thought Questions:

How might different meanings of the term *diagnosis* convey different information and treatment implications? What is the value of conceptualizing neurodevelopmental disorders as clinical manifestations of a common denominator, namely developmental brain dysfunction?

DEVELOPMENTAL PRINCIPLES

Development is an end product of neural function that unfolds over time as a result of 1) innate factors determined by the DNA sequence and heritable epigenetic modifications that make up an individual's biological endowment and 2) experiential influences that either affect neurodevelopment beneficially (e.g., environmental enrichment) or deleteriously (e.g., traumatic or hypoxic-ischemic brain insults or toxic stress) during sensitive periods of neuromaturation (Wang, 2018). The complex, dynamic processes that make up child development can be described clinically by quantifiable milestones and qualitative features and can be divided into three primary "streams" (also referred to as "domains") of development: motor, cognitive, and neurobehavioral. Each of the primary streams can be broken down into narrower streams of development, which can be assessed independently (Table 12.1). The motor stream includes gross and fine motor skills as well as oral motor function (e.g., chewing, swallowing, and motor aspects of speech). The cognitive, or central processing, stream includes receptive and expressive language abilities and nonverbal problem-solving/perceptual reasoning.

Table 12.1. Streams of development

Motor
Gross motor
Fine motor
Oral motor
Cognitive (or central processing)
Language
Receptive
Expressive
Nonverbal problem-solving/perceptual reasoning
Neurobehavioral
Social behavior
Adaptive emotional behavior, self-regulation, and mental status

The neurobehavioral stream includes fundamental aspects of social and emotional behavior, self-regulation, and mental status. These include the development of reciprocal social interaction, impulse control, attention, the development of an appropriately varied repertoire of interests and activities, and the development of adaptive regulation of mood and anxiety.

ATYPICAL PATTERNS OF DEVELOPMENT

Based on careful study of the development of thousands of infants and children, Gesell observed that typical development is methodical, orderly (sequential), timed, and therefore largely predictable (Gesell, Halvorsen, & Amatruda, 1940; Gesell & Amatruda, 1947). This principle is the basis for using developmental milestones and tests as markers of neuromaturation. Independent assessment of skills within each stream of development facilitates recognition of patterns of atypical development. The terms *delay*, *dissociation*, and *deviance* describe variations in the attainment of developmental milestones as manifestations of underlying brain dysfunction, and analysis of these three types of variation is helpful in distinguishing among diagnostic possibilities (Accardo, Accardo, & Capute, 2008; Capute & Palmer, 1980; Voigt, 2018; also see Chapter 11).

Developmental delay refers to a significant lag in the attainment of milestones in one or more areas of development; milestones are attained in the typical sequence but at a slower rate. Traditionally, a delay of 22.5%–25% or greater in the rate of development, or performance that is 1.5 to 2 standard deviations or more below the norm, has been considered to be significant. The developmental quotient (DQ) is a useful means of quantifying development within a stream as

a percentage of normal. The DQ is therefore a ratio; that is, the child's developmental age (DA) in a particular area of development divided by his or her chronological age (CA) and multiplied by 100 to yield a percentage ($DQ = DA / CA \times 100$). For example, a 20-month-old child who is found to have gross motor skills at the level expected of a typically developing 12 month old has a DQ in the gross motor stream of $12 / 20 \times 100 = 60$. This child can thus be said to be exhibiting a 40% delay in gross motor development or to be progressing at 60% of the typical rate within the gross motor stream. The functional DA equivalent is determined based on comparison to typical milestones in a particular area of development using tables of normal milestones that are available in textbooks (e.g., Accardo, 2008; Sonksen, 2016) and review articles (Scharf, Scharf, & Stroustrup, 2016) or assessment instruments that yield age equivalents in different streams of development, such as the Capute Scales (Cognitive Adaptive Test/Clinical Linguistic and Auditory Milestone Scale [CAT/CLAMS]; Accardo & Capute, 2005), the Parents' Evaluation of Developmental Status: Developmental Milestones (PEDS:DM; Brothers, Glascoe, & Robertshaw, 2008), and the Child Development Inventory (CDI; Ireton, 1992).

Developmental dissociation refers to a significant difference in developmental rates between two of the major areas of development: gross motor, fine motor, problem-solving, expressive language, receptive language, and social/adaptive. Typical sequences of development are maintained, but there is asynchrony, resulting in one or more areas of development being significantly out of phase with other areas. By convention, a DQ or rate discrepancy of greater than 15 percentage points between two major areas of development is typically considered to represent dissociation in infants or young children. In older children, a difference in standard scores of more than 1 to 1.5 standard deviations on standardized measures traditionally defines a significant discrepancy between academic achievement and intellectual ability (Peterson & Pennington, 2015; Shaywitz, Morris, & Shaywitz, 2008).

Developmental deviance refers to nonsequential unevenness in the achievement of milestones within one or more streams of development (e.g., within-task scatter). This phenomenon is typically described qualitatively, rather than as a rate, quotient, or standard score, although some investigators have attempted to quantify deviance in the form of intrasubtest scatter (inconsistent or unusual response patterns to test items within a single scale on a standardized test; Godber, Anderson, & Bell, 2000; VanMeter, Fein, Morris, Waterhouse, & Allen, 1997). Typical developmental sequences are not maintained, and deviance is intrinsically abnormal.

Whereas children exhibiting delay and dissociation attain milestones in a manner that would be expected for a younger typically developing child, deviance is not typical for any age.

GDD has often been defined in the literature as significant delays in two or more of the following domains: gross motor/fine motor, speech/language, cognition, social/personal, and adaptive functioning (i.e., activities of daily living; Moeschler & Shevell, 2014; Riou, Ghosh, Francoeur, & Shevell, 2009). According to this definition, a child with spastic diplegic cerebral palsy (CP) causing isolated motor delay and secondary adaptive deficits and an infant exhibiting 25% delays in expressive language and gross motor skills (with average receptive language and problem-solving abilities) would both be considered to have GDD. The assumption that having delays in any two domains is equivalent to having general intellectual delay is inherently problematic; for example, Riou and colleagues (2009) demonstrated that among preschoolers with a diagnosis of GDD, 73% had an IQ greater than 70 and 20% had average intelligence.

The alternate definition of GDD restricts its use to young children with significant delays in both language and nonlanguage cognition (problem-solving) accompanied by deficits in adaptive behavior (activities of daily living). This definition more closely approximates applying the concept of ID to children who may be too young to obtain a valid and reliable IQ measurement. In these children, continued development at the same trajectory would predict functioning within the ID range. Of course, this does not mean that all children with GDD will ultimately have ID because developmental trajectories may change, but the greater the degree of GDD, the higher the predictive validity of an early childhood diagnosis (Elbaum & Celimi-Aksoy, 2017; VanderVeer & Schweid, 1974). Consistent with the latter approach, in 2013 the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-5)* introduced GDD as a diagnostic classification to describe children under the age of 5 years who exhibit developmental delays “in several areas of intellectual functioning,” and categorized this diagnosis within the intellectual disabilities subgroup of neurodevelopmental disorders (American Psychiatric Association, 2013).

Once specific areas of delay have been identified, the concept of dissociation becomes particularly important in defining and distinguishing among the various developmental disability diagnoses. Mixed receptive and expressive language disorders, for example, are defined by language development that is delayed and dissociated from other streams of development, especially nonlanguage cognition/problem-solving. In the case of expressive language disorders, there is

dissociation between the expressive and receptive components of the language stream; expressive language development is delayed, but receptive language and nonlanguage cognition are intact. Specific learning disabilities are also determined by dissociation, or discrepancy; academic underachievement in a specific area (e.g., reading, mathematics, or written expression) is unexpected because the child appears to have all of the factors (i.e., intact sensory abilities, adequate intelligence and motivation, and exposure to reasonable instruction) needed to achieve but continues to struggle (Fletcher & Miciak, 2017; Peterson & Pennington, 2015; Shaywitz et al., 2008). In the past, discrepancy between academic achievement and intellectual ability (as measured by IQ) was used as the primary indicator of the presence of a specific learning disability. However, the weight of the evidence suggests that there is little difference between IQ-discrepant and nondiscrepant low-achieving children in achievement, behavior, cognitive processes (e.g., phonological awareness), prognosis, response to treatment, or neuroimaging markers of brain function (Fletcher & Miciak, 2017; Peterson & Pennington, 2015). Current approaches emphasize the discrepancy between actual and expected response to quality instruction, and IQ tests are not required for diagnosis of a specific learning disability (see Chapter 20; Fletcher & Miciak, 2017; Peterson & Pennington, 2015). Important components of a learning disability evaluation include assessment of academic achievement using well-validated standardized measures, instructional response, and contextual factors that interfere with achievement, such as other disorders (e.g., attention-deficit/hyperactivity disorder [ADHD]) or toxic stress (Fletcher & Miciak, 2017). Absolute developmental delay relative to age does not have to be present for dissociation to be significant, since, for example, a child with an IQ of 130 and standard scores of approximately 100 on measures of reading achievement may have a specific reading disability based on poorer-than-expected reading performance despite quality instruction (Gilman et al., 2013).

Developmental deviance may present in young children as failure to accomplish simple tasks or skills in a given developmental sequence while unexpectedly performing tasks that are more complex. For example, a 2-year-old child who can use single words to label more than 50 different objects or pictures and correctly identify colors and shapes, yet does not use words to make requests, does not say “mama” or “dada,” and still engages in immature jargonizing is exhibiting significantly deviant language development. Strong rote memory skills accompanied by weak comprehension and pragmatic (social) language skills may contribute to this deviant profile and may suggest the presence

of ASD (Boucher, 2012; Myers & Challman, 2018). Most individually administered standardized psychometric tests include items that are arranged hierarchically, so in order to be able to administer only the appropriate portion of the test to a particular child, a “basal” and a “ceiling” must be established. Typically, this means that the child must answer a certain number of consecutive items correctly to establish a basal, and the test is stopped when the child answers a certain number of consecutive items incorrectly (ceiling). Developmental deviance, especially in older children with learning disorders, may be suggested by a much-wider-than-average number of items between the basal and the ceiling on a particular test or subtest because of tending to pass more advanced items in the hierarchy while failing easier items (Accardo et al., 2008; Godber et al., 2000). Deviance in motor development may occur in children with CP due to abnormal muscle tone and control. For example, a child with spastic diplegia may be able to stand holding on and cruise along furniture before being able to sit independently.

Another phenomenon that may be detected by history or upon serial assessment is **developmental regression**, which is the loss of previously attained milestones. A child who has truly regressed developmentally is no longer capable of performing previously mastered skills. Regression may occur following a period of typical development or may be superimposed on preexisting atypical development (Baird et al., 2008; Meilleur & Fombonne, 2009). According to population-based studies, approximately 20% of children with ASD lose previously established language and/or social interaction skills at a mean age of 21–24 months (Barger, Campbell, & McDonough, 2013). The reported rate of regression is higher (35%–40%) in clinic-based samples and survey studies (Barger et al., 2013). However, the true prevalence of meaningful regression may be lower because these studies are plagued by problems with case definition and reliance on parent-reported skill loss without verification by rigorous clinical information gathering (Barbarese, 2016). In addition, very few cases of frank regression have been reported in prospective studies of high-risk infants (Jones, Gliga, Bedford, Charman, & Johnson, 2014). Although unexplained developmental regression is not unique to ASD, the available evidence suggests that it is more frequent in children with ASD than in those with other diagnoses such as GDD and specific language impairment (Baird et al., 2008; Pickles et al., 2009). However, the rate of developmental regression, including language regression, is also high (22%) in children with severe or profound congenital visual impairment (Dale & Sonksen, 2002). Landau-Kleffner syndrome, or acquired epileptic aphasia, is a rare epilepsy syndrome that affects otherwise typically

developing children between 3 and 7 years of age and involves loss of the ability to understand and use spoken language (Shbarou & Mikati, 2016). Most affected children also have clinical seizures (see Chapter 22). Global regression involving language, motor, and cognitive skills may indicate the presence of an inborn error of metabolism or neurodegenerative disorder, brain tumor, or subclinical seizures, and it therefore always warrants investigation (Greene, 2013; Kelley, 2008).

Specific types of isolated regression in motor skills, such as deterioration in gait in someone with a known disability, may be explained by the history and physical exam and warrant further evaluation and/or treatment. For example, deterioration in gait in a child or adolescent with spastic diplegia may be due to the mechanics of linear growth and weight gain in the setting of abnormal tone and the development of contractures requiring medical or surgical intervention. Similar deterioration in gait accompanied by increasing spasticity in the legs, change in bowel and bladder function, and progressive scoliosis in an individual with spina bifida would prompt evaluation for tethering or syrinx of the spinal cord.

Spectrum and Continuum of Developmental Disabilities

The various developmental disorders that result from neurologically based abnormalities in cognitive, motor, and neurobehavioral function have been referred to as the *spectrum* of developmental disabilities (Accardo et al., 2008; Voigt, 2018). Within each group of disorders, there also exists a spectrum of severity and prevalence. These conditions range from high-prevalence, low-severity conditions such as dyslexia/specific reading disability, developmental coordination disorder (DCD), and ADHD to low-prevalence, high-severity conditions such as ID and CP (Accardo et al., 2008; Boyle et al., 2011; Voigt, 2018). Severity is determined by the degree of developmental delay, dissociation, and/or deviance, and, as with most other pathologies, the milder forms are more common than the most severe forms.

In contrast to focal neurologic deficits that occur in the mature nervous system as a result of insults such as cerebrovascular accidents, developmental brain dysfunction tends to be diffuse, resulting in observable manifestations in cognitive, motor, and neurobehavioral functioning (Figure 12.1). Clinical developmental disability syndromes may be primarily cognitive (e.g., ID, a language disorder, or a specific learning disability), motor (e.g., CP or DCD), or neurobehavioral (e.g., ASD or ADHD) conditions, but careful examination typically reveals additional impairments in the other streams of development. In fact, the presence of

Figure 12.1. Adaptation of Capute's triangle: Developmental brain dysfunction impacts all three major streams of development. (Source: Capute, 1991)

additional impairments or coexisting disorders is the rule rather than the exception. This concept is referred to as the *continuum* of developmental disabilities.

The epidemiology of developmental disabilities supports the concept of a continuum across streams of development, as essentially all developmental disorders co-occur with other developmental disorders much more frequently than expected by chance. For example, data from population-based epidemiologic studies suggest that 31%–65% of children with CP also have an IQ less than 70 (Pakula, Van Naarden Braun, & Yeargin-Alsopp, 2009; Türkoğlu, Türkoğlu, Çelik, & Uçan, 2017; Yin Foo et al., 2013). Even among those individuals with CP but without ID, the prevalence of below-average IQ, learning disabilities, speech and language disorders, and ADHD is high (Odding, Roebroek, & Stam, 2006). ASD has been reported to occur in 6.9%–8.7% of children with CP (Christensen et al., 2014; Delobel-Ayoub, Klapouszczak et al., 2017). Insults causing brain dysfunction severe enough to result in CP also increase the risk of other neurological and sensory dysfunction; also increased in this population are rates of epilepsy (20%–46%), visual impairment (2%–19%), and hearing impairment (2%–6%) (Pakula et al., 2009). In addition, the neuromotor impairment associated with CP often leads to secondary associated conditions, such as orthopedic deformities, chronic constipation, gastroesophageal reflux, malnutrition, poor growth, osteopenia, and skin breakdown (see Chapter 21).

The developmental profile can be conceptualized as an iceberg, with one or more visible tips representing the defining features of the primary diagnoses, and the submerged portion representing the larger continuum of manifestations of underlying brain dysfunction

(Accardo et al., 2008). For example, a child with ADHD, by definition, exhibits symptoms of inattention and/or hyperactivity/impulsivity that are inappropriate for age and developmental level and that interfere significantly with functioning. However, the ADHD symptoms (tip of the iceberg) are usually accompanied by other signs and symptoms below the surface, such as motor coordination deficits, tics, neurologic “subtle” or “soft” signs upon examination, learning deficits, pragmatic language impairment, social skills deficits, sleep problems, obsessive thoughts, compulsive behaviors, anxiety, depressed or irritable mood, and disruptive behaviors. These are manifestations of the underlying brain dysfunction and its interaction with environmental influences and experiences. Often, some of these symptoms of neurological dysfunction are prominent enough to meet diagnostic criteria for one or more other disorders, such as a specific learning disability, DCD, Tourette syndrome, obsessive-compulsive disorder, or oppositional-defiant disorder (additional visible tips of the iceberg). Other symptoms may remain subthreshold in terms of additional diagnoses but may still be important to address when planning treatment.

Comorbidity among developmental disorders is primarily due to the diffuse nature of the underlying brain dysfunction, which is often genetic in origin, although environment and experience may be important modifiers of this effect. For example, studies of twins have shown that reading disorder (RD), math disorder (MD), and ADHD are familial and heritable and that the etiology of the comorbidity between RD and MD (28%–64%), RD and ADHD (10%–40%), and MD and ADHD (12%–36%) is primarily explained by common genetic influences (Willcutt et al., 2010). A genetic abnormality may result in different phenotypes due to incomplete penetrance, variable expressivity, or interactions between genes and the environment. A gene/environment ($G \times E$) interaction is said to occur if environmental circumstances modify the expression of an individual's genetic background, either strengthening or weakening the phenotype. Significant $G \times E$ interactions have been described in psychiatric conditions such as conduct disorder and depression and are being explored in developmental disabilities such as ADHD and ASD (Willcutt et al., 2010).

DIAGNOSTIC CLASSIFICATION

Diagnostic labels, whether *disease* names that imply a known etiology or pathophysiology or *disorder* names that are defined by clusters of attributes or symptoms less closely related to a single cause, are the usual means by which clinicians access the relevant medical literature to guide management decisions and communicate

about conditions with patients, families, and colleagues (Clark, Cuthbert, Lewis-Fernández, Narrow, & Reed, 2017). Diagnostic classification is important for treatment planning, prognostication, and other aspects of clinical care for specific individuals as well as for etiologic and outcomes research and societal allocation of resources (Table 12.2).

In most branches of medicine, systematic classification systems based on etiology and pathophysiology predominate; conditions are differentiated first by cause (e.g., infectious, genetic, neoplastic, autoimmune, or traumatic) and second by how these processes disturb organ structure and function (e.g., pneumonia, skeletal dysplasia, leukemia, hepatitis, or brain injury). In developmental medicine and psychiatry, however, conditions are described primarily phenomenologically as disorders or symptom-cluster syndromes rather than as diseases with known causes (Clark et al., 2017; Hyman, 2010). Although categorization based on phenomenology is useful for establishing a common language that can be applied with reasonably good interrater reliability, limitations of this approach for capturing clinical and biological realities are apparent based on the within-disorder etiologic heterogeneity (multiple causality), high rates of comorbidity among disorders, shared risk factors and etiologies across disorders, scientifically arbitrary nature of diagnostic thresholds,

and large numbers of individuals who have substantial impairment but do not quite fulfill the diagnostic criteria (Clark et al., 2017; Hyman, 2010; Lilienfeld & Treadway, 2016; Moreno-De-Luca et al., 2013).

While a definitive etiologic diagnosis can be made in a subset of individuals with any developmental disorder, there is not a one-to-one correspondence between a developmental disorder diagnosis and etiologic diagnosis. Chromosomal microarray analysis and next-generation sequencing studies have made it clear that there is substantial genetic overlap between and among neurodevelopmental disorders; for example, the same pathogenic copy number variants and single nucleotide variants have been detected in individuals with ASD, ID, epilepsy, schizophrenia, and other clinical presentations (Coe, Girirajan, & Eichler, 2012; Gonzalez-Mantilla, Moreno-De-Luca, Ledbetter, & Martin, 2016; Moreno-De-Luca et al., 2013). Neurodevelopmental disorders, which share overlapping symptoms and risk factors and frequently co-occur, can be conceptualized as clinical manifestations of a common denominator, “developmental brain dysfunction,” rather than causally and pathophysiologically distinct entities (see Box 12.1; Gonzalez-Mantilla et al., 2016; Moreno-De-Luca et al., 2013).

Levels of Diagnosis

Disorders of development and behavior can be described at three different levels, each of which has clinical significance (see Figure 12.2; Table 12.3). This conceptualization is shown in Figure 12.2 as an inverted triangle, with the broad first level (specific impairments) at the top, narrower second level (categorical diagnoses) in the middle, and very narrow third level (etiologic diagnosis) at the bottom. An individual may have many specific impairments or symptoms that identify a smaller number of categorical disorders or symptom-cluster syndromes that are due to one underlying etiology or a very small number of distinct etiologies.

Specific Impairments The first level of diagnosis, which is descriptive and may not be traditionally thought of as representing a diagnosis at all, is the level of identifying and labeling pertinent signs and symptoms as specific impairments or deficits. A prerequisite for formulating categorical diagnoses (disorders or symptom-cluster syndromes), delineation of functionally impairing symptoms is essential for treatment planning, since educational, behavioral, and psychopharmacologic interventions most often address these specific impairments rather than the categorical diagnostic classification or etiologic diagnosis

BOX 12.1 EVIDENCE-BASED PRACTICE**The Research Domain Criteria Initiative**

Significant challenges to the validity of current diagnostic classification systems include the high rates of comorbidity among disorders, the scientifically arbitrary nature of diagnostic thresholds, the large number of patients who have substantial impairment but are subthreshold for diagnosis, and the imprecise relationships between etiologies and diagnoses (Clark et al., 2017; Hyman, 2010; Lilienfeld & Treadway, 2016). In recent years, advances in genetic testing and the application of the new technologies to well-characterized patient cohorts have resulted in increasing recognition that often a clinical disorder can have multiple different genetic causes (etiologic heterogeneity) and that a particular genetic variant can cause multiple different clinically distinct disorders (variable expressivity; Moreno-De-Luca et al., 2013; Stessman, Turner, & Eichler, 2016).

In response to these issues, the National Institute of Mental Health launched the Research Domain Criteria (RDoC) initiative to develop for research purposes new ways of classifying developmental and psychiatric disorders based on dimensions of observable behavior and neurobiological measures (Cuthbert, 2015; Insel et al., 2010). The RDoC approach employs a dimensional rather than categorical framework, is transdiagnostic in seeking markers of neural dysfunction, and is translational in emphasis (Clark et al., 2017; Cuthbert, 2015; Cuthbert & Insel, 2013; Insel et al., 2010; Lilienfeld & Treadway, 2016). The goal is to identify brain mechanisms that explain the etiology and pathophysiology of these disorders, leading to earlier and more accurate diagnosis; prediction of treatment responses and outcomes; and, ultimately, development of more effective treatments that are based on neurobiology rather than symptoms (Insel et al., 2010). The RDoC initiative neither replaces nor excludes other classification systems; it is a paradigm designed to promote research that facilitates application of neuroscience to diagnostic classification, providing scaffolding for a large-scale research program that may ultimately yield an alternative to the *Diagnostic and Statistical Manual of Mental Disorders* and the *International Classification of Diseases* (Cuthbert, 2015; Lilienfeld & Treadway, 2016).

(Myers & Challman, 2018; Myers, Johnson, & Council on Children with Disabilities, 2007).

It is the specific deficits that are addressed, for example, by educational and habilitative interventions, with

the goal of building developmentally appropriate skills and increasing functional independence. Challenging behaviors and symptoms associated with developmental disabilities (e.g., aggression, self-injurious behavior,

Figure 12.2. Levels of diagnosis. (Key: ADHD, attention-deficit/hyperactivity disorder.)

Level of Diagnosis	Importance					
	Treatment		Genetic counseling	Identification of associated medical problems	Prognostication	Resource allocation
	Behavioral, educational	Psychopharmacologic				
Specific impairments	++	++	–	–/+	+ / ++	+
Categorical diagnoses	+	+	+	+	++	++
Etiologic diagnosis	–	–/+*	++	++	+	–/+

Key: –, minimal or no importance; +, important; ++, very important; *emerging importance (may become very important with future advances).

property destruction, elopement, compulsions, and others) may interfere with functioning and contribute substantially to the burden on families. In most cases, problem-focused behavioral interventions informed by functional behavior assessment are an important and effective component of treatment (Hanley, Iwata, & McCord, 2003; Harvey et al. 2009; McGuire et al., 2016; see Chapter 34). These interventions address the specific observable behaviors, not the diagnostic classification.

Even psychopharmacologic treatments are often determined more by the specific impairments or target symptoms than by categorical or etiologic diagnoses. The traditional psychiatric model of psychopharmacologic decision making involves first making the diagnosis of a specific disorder, such as ADHD or depression, and then choosing a medication based on that diagnosis. However, because symptoms exist on a continuum and occur across different disorders, and modifications of diagnostic criteria are necessary in order to apply many psychiatric diagnoses to individuals with more severe disabilities, the value of categorical distinctions in selecting pharmacologic treatment is often unclear. Therefore, a target-symptom approach is often the most appropriate treatment strategy (Accordino et al., 2016; Bostic & Rho, 2006; Myers, 2007; see Chapter 28).

In addition to considering impairments that are intrinsic to the individual, it is important to also consider the child's abilities and the practical impact of environmental, early experiential, and societal factors. The International Classification of Functioning, Disability, and Health for Children and Youth classification system focuses on impairment and enablement in body structures and functions, activities, and participation/involvement, as well as the influences of environmental and personal factors, that would be described at this level of diagnosis (Msall & Msall, 2008; Wolraich and Drotar, 2008).

Categorical Diagnoses: Disorders, Symptom-Cluster Syndromes

The second level of diagnosis involves recognizing patterns of specific impairments as disorders or clusters of symptoms that represent clinical syndromes (e.g., ADHD, ASD, ID, and mixed receptive-expressive language disorder) and categorizing them as such. This is the primary way that developmental disability diagnoses are classified using the *International Classification of Diseases* (ICD-10; World Health Organization, 1992) and *DSM-5* (American Psychiatric Association, 2013) diagnostic classification systems. Although there are significant weaknesses, as described previously, categorical diagnoses are reasonably reliable and very useful for communication. Identification of the categorical diagnoses is important for guiding and attempting to standardize treatment; identifying associated problems that meet threshold for a diagnostic label; providing a prognosis; and communicating information to patients, families, and treatment providers, including educators, habilitative therapists, psychologists, and health care providers. Epidemiologic information is also most often collected at this level of diagnosis, and this information can be used to guide resource allocation.

Etiologic Diagnosis

The third level of diagnosis, the etiologic diagnosis, involves identifying the specific underlying cause of the developmental disorder, which may be genetic, metabolic, teratogenic, infectious, hypoxic-ischemic, traumatic, a combination of more than one of these, or unknown/idiopathic. This etiologic level of diagnosis is commonly determined in individuals with disorders of the spinal cord, peripheral nervous system, or sensory deficits (such as blindness or deafness); this level of diagnosis currently can be determined in only a minority of individuals with brain-based developmental disabilities. In general, the

more severe the brain-based developmental disability, the more likely a specific etiologic diagnosis can be identified. For example, among individuals with ID, a specific etiology is much more likely to be determined if the cognitive impairment is severe (defined as an IQ less than 50) than if it is mild (an IQ between 50 and 70) (D'Arrigo et al., 2016; Yeargin-Allsopp et al., 1997). With the development of chromosomal microarray analysis and next-generation sequencing, the diagnostic yield of genetic testing has increased to 55%–70% for severe ID (Vissers, Gilissen, & Veltman, 2016).

The etiologic diagnosis is important, especially in the case of genetic disorders for which accurate counseling regarding recurrence risk can be provided and, in some cases, associated medical problems can be identified, treated, and perhaps prevented as a result of their known association with the genetic abnormality. For example, a child who is found to have a 22q11.2 deletion (see Appendix B) as the cause of his or her ID or ASD is at increased risk for cardiac, palatal, immune, and renal anomalies, as well as psychiatric disorders, and there is a 6%–10% chance that one of the parents has the deletion (McDonald-McGinn & Sullivan, 2011). If a parent is affected, he or she has a 50% chance of passing the deletion to each of his or her children. In addition, individuals with the 17q12 recurrent deletion are at risk for structural and functional renal disease and maturity-onset diabetes of the young, type 5, and require monitoring (Mitchel et al., 2016), and in the case of certain genetic epilepsies, knowing the etiologic molecular diagnosis allows important refinement of antiepileptic therapy decisions (Poduri, 2017).

The value of determining an etiologic diagnosis is not limited to genetic disorders that directly affect neurological function, and genetic tests are not the only valuable studies. For example, brain imaging may reveal an **infarction** as the cause of a young child's hemiplegia. This would prompt further evaluation that might identify a constitutional **coagulopathy** (clotting disorder) for which additional treatment, stroke recurrence risk counseling, and family genetic counseling are available. An infant with congenital cytomegalovirus infection requires serial assessments for hearing loss, which may be delayed in onset and/or progressive, and in the case of certain inborn errors of metabolism, neuroprotective or even curative treatment can be provided if the diagnosis is made early (see Chapter 16).

All of these important aspects of medical management are more closely linked to etiologic diagnosis than to categorical (level 2) diagnoses or specific impairments (Table 12.3). Discoveries about the neurobiology of genetic neurodevelopmental disorders have led to pharmacological interventions to improve cognitive function in animal models of various disorders,

and with human clinical trials for single-gene disorders, such as tuberous sclerosis complex, fragile X syndrome, and Rett syndrome, we have entered the era of neuroscience-driven pharmacotherapy that depends on the etiologic diagnosis rather than the disorder- or symptom-level diagnosis (Jeong & Wong, 2016; van Karnebeek, Bowden, & Berry-Kravis, 2016).

THE DIAGNOSTIC PROCESS

Similar to other areas of medicine, the diagnostic process in developmental medicine consists of taking a history, completing a physical examination, generating a differential diagnosis, planning tests and investigations, formulating a provisional or definitive diagnosis, and developing a management plan. However, in developmental medicine, the examination includes developmental and/or psychoeducational testing as an extension of the neurologic exam. In addition, there are essentially two levels of differential diagnosis: one addressing the categorical diagnosis (e.g., ID or ASD) and the other addressing the etiologic diagnosis (e.g., 22q11.2 deletion syndrome or fragile X syndrome). Laboratory tests and other investigations such as neuroimaging and neurophysiologic studies primarily address the etiologic differential diagnosis or medical conditions that may be associated with the categorical diagnosis.

The diagnostic evaluation format will vary depending on the availability of local resources and clinician preferences. One approach involves employing an interdisciplinary or multidisciplinary team specializing in developmental disabilities. This includes individuals from a variety of disciplines including psychology, speech-language pathology, occupational therapy, physical therapy, special education, social work, audiology, and various medical subspecialties. Alternatively, the diagnostic evaluation may be conducted by an individual clinician-specialist who is capable of interpreting and integrating information from various disciplines and comfortable with making developmental diagnoses, even if there is not an interdisciplinary team that meets in person. Most often, this is a neurodevelopmental pediatrician, developmental-behavioral pediatrician, child psychologist, neuropsychologist, child and adolescent psychiatrist, or pediatric neurologist.

The diagnostic evaluation should incorporate the following elements (Davie, 2012; Huerta & Lord, 2012; Myers & Challman, 2018; Steiner, Goldsmith, Snow, & Chawarska, 2012):

1. *Caregiver interview*, including a thorough medical history and review of systems, a developmental and behavioral history (past milestone attainment

and current abilities), a social history, and a three-generation family history. Standardized rating scales completed by parents/caregivers and teachers or other professionals are commonly used to quantify symptoms and compare them to normative populations.

2. *Review of pertinent medical and educational records*, including any available standardized testing done by early intervention evaluators, psychologists, speech-language pathologists, occupational therapists, physical therapists, and special educators. Although not necessary for categorical diagnosis, it is helpful to note the results of any previous etiologic investigations and other pertinent tests that have been completed (e.g., genetic testing, audiometry, and central nervous system [CNS] imaging).
3. *Direct clinical assessment*, including a physical examination (with an emphasis on the neurologic examination and evaluation for **dysmorphology**), developmental/psychological testing (appropriate for age and level of ability), and neurobehavioral observation/elicitation. In the case of team evaluations, the developmental or psychoeducational testing is often completed by someone other than the physician. In some cases, even a physician diagnostician who is working independently will review and interpret the results of current standardized testing performed by professionals in other disciplines in lieu of directly administering tests herself/himself.
4. *Integration of information and determination of categorical diagnoses*, most often using current criteria from the *DSM-5* (American Psychiatric Association, 2013) or the *ICD-10* (World Health Organization, 1992), although the diagnostician is not limited to these classification systems. Clinical judgment is informed by the information gathered in steps 1 to 3.
5. *Consideration of etiologic possibilities* and determination of appropriate investigations to evaluate for etiologic diagnoses and/or associated medical conditions.

Many clinicians choose to gather some historical information in advance by having parents complete medical, developmental, and family history questionnaires, which allows consultation time to be used for more focused questioning (Davie, 2012; Horridge, 2011). This process may also increase the accuracy of historical information because it gives families the opportunity to reflect on the questions without pressure or time constraints, to review milestones in baby books or journals, and to ask relatives about family history. In some

practice models, the diagnostic process involves more than one office visit.

Chief Complaint and Age of Presentation

In all branches of medicine, the physician starts the diagnostic process by asking about the presenting symptoms and concerns, or the “chief complaint.” In the field of developmental disabilities, the age of presentation/referral to the developmental specialist is closely tied to the nature of the chief complaint and developmental diagnosis (Lock, Shapiro, Ross, & Capute, 1986; Shapiro & Gwynn, 2008; Shevell, Majnemer, Rosenbaum, & Abrahamowicz, 2001). Although caregivers may detect severe hearing or vision impairment in infants at 3–6 months of age based on a lack of appropriate response to sounds or visual tracking, concerns arising in the first 6 months of life are usually based not on developmental delays, but rather on medical risk factors. These include major congenital anomalies; obvious dysmorphic features; failed newborn hearing screening; or known central nervous system insults, such as severe intraventricular hemorrhage or hypoxic-ischemic encephalopathy. Physiologic instability resulting from frequent seizures, feeding dysfunction, or poor weight gain may also trigger concerns about development in early infancy. Concerns presenting at 6–18 months of age are most often related to delayed attainment of gross motor milestones, and common diagnoses include CP and other types of neuromotor dysfunction, including central hypotonia and neuromuscular disorders (Crawford, 1996; Ehrmann Feldman et al., 2005; Lock et al., 1986; Shevell et al., 2001).

Children with delayed language development tend to present at 18–36 months of age, and common diagnoses among this group include language disorders, GDD/ID, and ASD. Toddlers with both delayed language and problem-solving skills (GDD) tend to present for diagnostic evaluation slightly earlier than those with primary language disorders (median ages 27 months and 32 months, respectively; Lock et al., 1986). One study found that among 17- to 36-month-old children with ASD receiving early intervention services in Louisiana, the most common first concern reported by parents was delayed communication (74%), followed by challenging behaviors (24%) and social skills deficits (12%) (Kozlowski, Matson, Horovitz, Worley, & Neal, 2011). However, communication impairment was also the most frequent initial concern reported by parents of toddlers with other developmental disorders (81%), and no single area of concern distinguished ASDs from other developmental disorders.

Disruptive behaviors, including tantrums, oppositional and defiant behaviors, impulsivity, hyperactivity, and aggressive or destructive behavior, can present over

a wide range of ages, from 24 months to school age and beyond. These behaviors are associated with a variety of developmental and behavioral diagnoses. Whereas the hyperactivity and impulsivity of ADHD, combined presentation (ADHD-C) may prompt referral in the pre-school period, children with predominantly inattentive presentation ADHD (ADHD-I) typically are not recognized until inattention, distractibility, and poor organizational skills interfere with academic functioning in elementary school or later (see Chapter 19). Individuals with ADHD-I tend to manifest impairment later (after age 7 in 43%), have primarily academic problems, and exhibit fewer social and behavioral problems than those with ADHD-C (Applegate et al., 1997). Concerns about academic achievement or school performance may present as early as age 3–5 years in these children, but these issues more commonly arise as problems in the elementary school years or later. As a result, learning disorders or disabilities are primarily diagnosed in school-age children or adolescents with ADHD.

Information Gathering

The Medical History A careful prenatal and perinatal history may identify risk factors, such as toxic or teratogenic exposure, premature birth, or maternal complications (e.g., infection, gestational diabetes mellitus, pregnancy-induced hypertension, hypothyroidism, or other significant illness; Bellman et al., 2013; Horridge, 2011; Whitaker & Palmer, 2008). In addition to eliciting any potential history of perinatal hypoxic-ischemic insult, the clinician may identify markers of fetal abnormality, such as hypoactive or hyperactive fetal movements, evidence of distress noted on fetal monitoring, breech presentation, or abnormal brain/body growth (i.e., microcephaly, macrocephaly, and small for gestational age status). The neonatal history is focused on identifying pertinent complications and treatments, especially in infants who were born prematurely and/or had medical or surgical problems requiring intensive care, and eliciting evidence of nonspecific neurobehavioral or neuromotor abnormalities that may provide insight into the integrity of the CNS. Examples of the latter include excessive quietness, irritability, persistent colic, altered sleep–wake cycle, feeding problems, jitteriness, floppiness, and stiffness. Complications such as intraventricular or **parenchymal** CNS hemorrhage, **periventricular leukomalacia**, neonatal seizures, severe hyperbilirubinemia, chronic lung disease associated with prematurity (especially with early postnatal steroid treatment), and retinopathy of prematurity should be noted (see Chapters 5 and 25).

The medical history beyond the neonatal period is also helpful in establishing risk and providing clues to the etiology of developmental problems (Bellman et al., 2013; Whitaker & Palmer, 2008). Pertinent findings include past acute medical conditions (e.g., meningitis, encephalitis, and traumatic brain injury), chronic illnesses that have the potential to impact development and behavior (e.g., malnutrition, recurrent infections, cancer, sickle-cell anemia, and chronic renal disease; see Chapter 24), and environmental exposures (e.g., lead; see Chapter 2). The medical history may also provide clues suggesting the possibility of a metabolic disorder (e.g., episodic neurological dysfunction, unusual prostration with illness, or intolerance of fasting) or genetic syndrome (e.g., congenital anomalies such as congenital heart defects, cleft palate, or **hypospadias**). Specific prompts are often required to elicit all of the pertinent issues from parents; important medical problems may be omitted by parents unless there is a specific review of systems and inquiry about hospitalizations or other medical consultants who have participated in the child's care. It is especially important to inquire whether the child has had formal hearing and vision screening. Sometimes anomalies that were surgically corrected are not mentioned by parents until the clinician inquires specifically about previous surgical procedures.

Developmental and Behavioral History A thorough and accurate developmental and behavioral history requires substantial skill, experience, and time to complete, but it is usually the most informative aspect of the neurodevelopmental diagnostic assessment (Davie, 2012; Horridge, 2011; Leppert, 2011; Montgomery, 2008; Whitaker & Palmer, 2008). The components of the developmental and behavioral history are outlined in Table 12.4. Developmental milestones (see Chapter 11) are the cornerstones of the developmental and behavioral history; they provide the information necessary to identify developmental delays and atypical patterns of development, including dissociation, deviance, and regression, as described previously.

Useful milestones must have precise definitions, occur within a narrow normative time frame, be clinically observable and useful to the child, and have predictive validity (Accardo et al., 2008; Bellman et al., 2013; Shapiro & Gwynn, 2008). Questions about current abilities should seek more detail than those on past milestones, which should focus on more notable milestones that are easier to recall by parents. When eliciting a current history of babbling in an infant, for example, the clinician must first define for the parent

Table 12.4 Developmental and behavioral history

Age of developmental milestone attainment and current functioning	
Gross motor skills	Academic achievement (strengths, weaknesses)
Fine motor skills	Social skills
Communication/language skills (receptive, expressive, pragmatic)	Adaptive skills (self-care, activities of daily living)
Problem-solving skills/nonlanguage cognition	Play/leisure skills and interests
Identification of atypical developmental patterns	
Delay, dissociation, deviance	
Regression	
Adaptive and maladaptive emotional behavior, self-regulation, and mental status	
<i>Challenging behaviors</i>	<i>Sensory modulation issues (tactile, auditory, visual, olfactory, vestibular)</i>
Inattention, distractibility	Overresponsivity
Disorganization	Underresponsivity
Hyperactivity	Sensation-seeking, unusual sensory exploration
Impulsivity	<i>Food- or meal-related problems, pica</i>
Noncompliance, oppositional and defiant behavior	<i>Sleep problems</i>
Tantrums, emotional outbursts	Difficulty falling asleep, bedtime resistance
Aggression	Nightwakings
Self-injurious behavior	Early morning awakening
<i>Repetitive behaviors</i>	Snoring, gasping, apnea
Stereotypy	Excessive sleep
Obsessions	<i>Anxiety</i>
Compulsions	<i>Mood problems</i>
Perseveration	Depression, mania, irritability, lability
Rituals, nonfunctional routines	<i>Conduct problems</i>
Tics	Lying, stealing, truancy, vandalism, cruelty to animals, fire setting
	<i>Enuresis, encopresis</i>

that babbling is consonant-vowel combinations. Then they can explore where the child is in the hierarchy of babbling, which typically progresses from single syllables (“da”) to reduplicative strings (“dadada”) of varying length. This is followed by an increased repertoire of reduplicative strings (“dadada,” “bababa,” or “gagaga”) and then nonreduplicative strings (“badabagaba”). If the child were a 3 year old who is speaking in phrases, the clinician would not go into this level of detail about babbling while eliciting the expressive language history because this is not something that parents would be likely to recall. The clinician would instead focus on milestones such as when the first meaningful words were spoken and when the child began to use novel two-word combinations. More detailed questions are reserved for current abilities (e.g., vocabulary, length

and content of phrases and sentences, use of pronouns, use of plurals, and intelligibility).

The experienced diagnostician not only has a thorough knowledge of the average age of attainment of milestones in all areas of development, but is also able to improve parent recall of developmental achievements by linking them to important family events. This might include asking about function during past holidays, birthdays, or summer vacations (e.g., “How was your child moving around on her first birthday? Was she crawling, pulling up to a standing position, cruising along furniture, or walking independently?”). Each area of development is reviewed chronologically to ascertain the age at which specific important milestones were attained as well as the current level of functioning (Leppert, 2011; Whitaker & Palmer, 2008).

This approach allows retrospective analysis of developmental rate in each stream and recognition of changes in trajectory over time, such as improving trajectory (“catch-up”), plateau, or regression. This is analogous to obtaining past growth measurements and plotting them on appropriate growth curves to facilitate recognition of important patterns, such as crossing percentiles due to a plateau in linear or head circumference growth or loss of weight.

It is also important to thoroughly explore whether there are challenging or maladaptive behaviors and, if so, to obtain specific descriptions of the challenging behaviors (Table 12.4). Standardized rating scales may be helpful in eliciting and quantifying various aspects of behavior from different sources, including parents and teachers, but they are not independently diagnostic and should not replace the clinician interview (American Academy of Pediatrics, Task Force on Mental Health, 2010). If the child exhibits challenging disruptive behaviors such as tantrums or aggressive outbursts, for example, it is important to specifically describe 1) the specific behaviors (e.g., screaming, crying, throwing things, hitting, kicking, and dropping to the floor and flailing arms and legs); 2) their frequency, intensity, and duration; 3) exacerbating factors/triggers (e.g., time, setting/location, demand situations, denials, and transitions); 4) ameliorating factors and response to behavioral interventions; 5) time trends (increasing, decreasing, or stable); and 6) degree of interference with functioning. In this way, it is often possible to formulate working hypotheses about the functions of the behaviors and what aspects of the environment are maintaining these behaviors through inadvertent reinforcement (see Chapters 27 and 34). A published practice pathway for the evaluation and management of irritability-related challenging behavior in ASD includes a stepwise approach to collecting this type of information and a detailed checklist that can be applied to other diagnoses and behavioral symptoms (McGuire et al., 2016). Ultimately, after the child’s developmental functioning in all major streams has been assessed, it is possible to judge whether the behaviors that concern the parent are inappropriate for the child’s developmental level or whether they are actually typical behaviors once understood in the context of the child’s developmental level of functioning or “developmental age.” For example, parents who express concern and frustration about their 6-year-old child’s inattention, impulsivity, tantrums in response to denials, and nocturnal enuresis may begin to understand the behaviors and approach them more appropriately when they are put in the context of the child’s developmental age of 3 years.

Family History The primary goal of the family history, which should include at least three generations, is to identify genetic risk and clues to specific genetic etiology, including pattern of inheritance (Pyeritz, 2012; Saal & Chen, 2013). Parental ages at conception, history of prior fetal losses, educational levels, early educational difficulties, and major medical problems should be queried. Family history should include known genetic conditions; malformation syndromes; structural birth defects; and developmental and neurological disorders such as ID, ASD, CP, muscular dystrophies, ADHD, learning disorders, language disorders, developmental delays, epilepsy, tic disorders, hearing loss, and blindness (Hoyme, 2013; Saal & Chen, 2013). It is also often helpful to ask about whether any past family members were slow learners, required special education services or any extra help in school, needed a wheelchair for mobility, or were unable to live independently as adults. Psychiatric conditions, such as schizophrenia, depression, bipolar disorder, anxiety disorders, obsessive-compulsive disorder, and substance abuse, should also be explored.

The pattern of individuals with ID in a family, for example, may suggest autosomal dominant, autosomal recessive, X-linked, or mitochondrial inheritance (see Chapter 1). Even in the absence of any other family members with major developmental disabilities, the presence of other conditions may point to a specific genetic etiology. For example, a history of anxiety and difficulty with math in the mother and an undiagnosed tremor and ataxia syndrome in the maternal grandfather of a boy with GDD, hyperactivity, and gaze avoidance raises the possibility of fragile X syndrome (see Chapter 15). Factors such as ethnicity; consanguinity; and a history of multiple fetal losses, infant deaths, progressive or neurodegenerative disorders, or conditions associated with abnormal energy metabolism (e.g., myopathy, myoclonic epilepsy, cardiomyopathy, retinitis pigmentosa, ophthalmoplegia, sensorineural deafness, or peripheral neuropathy) may suggest an increased risk of metabolic disease (Greene, 2013; Kelley, 2008).

Social History Potential protective and deleterious psychosocial and socioeconomic factors should be explored. Parental education, cultural beliefs, family support systems, and previous experience with people with disabilities may impact the ability and willingness of parents or grandparents and extended family members to accept the diagnosis and treatment recommendations (see Chapter 37). A history of abuse or neglect of the child may be particularly relevant to

the interpretation of the child's behavior, attachment, and social functioning; previous involvement with child protective service agencies or foster care should be queried. Psychosocial stressors, such as recent crises or transitions, financial or marital difficulties, and mental health or substance abuse issues, may impact the child's development and behavior and the ability of the family to access resources and comply with treatment recommendations. If there are behavioral concerns about the child, it is important to determine the parents' expectations and behavior management strategies.

The child's educational/habilitative intervention history is also important. This includes utilization of early intervention services, preschool programs (including Head Start), and special education services. Any history of grade retention should be noted. Details of the current educational program should always be explored because a significant mismatch between educational expectations or demands and the child's current abilities is likely to result in poor progress and often behavioral or emotional problems, especially in school-age children. The timing and types of concerns voiced by the teachers and other school staff should be noted, along with previous disciplinary actions, such as frequent loss of recess or other privileges, after-school detention, or suspension from school.

Physical Examination The diagnostic evaluation should include a complete general physical and neurological examination. Particularly important aspects of the general physical examination include assessment for abnormal growth, dysmorphic features, evidence of visceral storage such as **hepatomegaly** (enlarged liver) and **splenomegaly** (enlarged spleen), and skin manifestations of neurocutaneous disorders or other genetic syndromes (Greene, 2013; Hoyme, 2013).

Aberrations in growth such as short stature, tall stature, obesity, microcephaly, and macrocephaly may provide important clues to the etiology of the developmental disability (Hoyme, 2013). For some underlying causes, such as hypothyroidism, effective treatment is available. Important alterations in the trajectory or velocity of growth may be exposed by plotting serial measurements on normal population growth curves, revealing crossing of multiple percentile lines. For example, an infant with a rapidly increasing head circumference may have hydrocephalus and require surgical intervention. A plateau in head growth after 6 months of age resulting in acquired microcephaly in a female infant in the second year of life may be a manifestation of Rett syndrome. The visible change

over time on the growth curve is much more informative than just a single measurement at the time of evaluation.

The child also should be examined for congenital anomalies, which can be classified as major or minor. Major anomalies usually require medical or surgical intervention, whereas minor anomalies generally do not require intervention but may be of cosmetic concern and diagnostic significance (Toriello, 2008). Major and minor anomalies occur much more commonly in children with developmental disabilities than in typically developing children. In individuals with three or more minor anomalies, the chance of having a major anomaly, a dysmorphic syndrome, or both increases greatly (Hoyme, 2013; Toriello, 2008). Measurements should be recorded and compared with normative values in order to confirm or refute clinical impressions of abnormal size, proportions, or spacing of body parts (Gripp, Slavotinek, Hall, & Allanson, 2013). A clinical impression of **hypotelorism** (eyes close together), for example, should be confirmed by measurements because it is a strong indicator of abnormal brain development. Findings such as a **submucosal** cleft palate are important not only because of the treatable impact on speech, feeding, and conductive hearing loss, but also as a clue to an underlying genetic syndrome such as 22q11.2 deletion syndrome. Documentation of detailed descriptions of anomalies is useful for later searching the literature and online databases for potential diagnoses, which can in turn lead to a reasonable approach to laboratory testing (Greene, 2013; Hoyme, 2013; Toriello, 2008).

Coarse facial features, a large tongue, corneal clouding, hepatomegaly, and splenomegaly may be due to a lysosomal storage disease (e.g., mucopolysaccharidoses or Gaucher disease) (Greene, 2013; Kelley, 2008; see Chapter 16 and Appendix B). In all children, the skin should be carefully examined, along with the other accessible ectodermal derivatives (hair, teeth, and nails). Hyperpigmented or hypopigmented lesions, vascular anomalies, and other lesions such as various types of fibromas and hamartomas are prominent aspects of neurocutaneous syndromes such as neurofibromatosis, tuberous sclerosis, Sturge-Weber syndrome, ataxia-telangiectasia, and incontinentia pigmenti (Korf & Bebin, 2017; Ruggieri & Praticò, 2015; see Appendix B). Linear streaks or whorls of hypopigmentation, sometimes referred to as hypomelanosis of Ito, are often associated with mosaicism for a variety of chromosomal abnormalities (Ruggieri & Praticò, 2015; see Chapter 1).

The neurologic examination of children with developmental disabilities includes standard evaluation of cranial nerve function, posture/station, muscle

strength, muscle tone, deep tendon reflexes, cerebellar function, gait, coordination, and sensation. Abnormalities such as unusual movements; pathological reflexes; and significant asymmetry of function, strength, tone, or deep tendon reflexes are recorded. In infants and young children, markers of neuromotor maturation, such as primitive reflexes and postural reactions, should be examined (Blasco, 1992). Older children are assessed for markers of neuromaturation and neurodysfunction, such as upper extremity posturing during stressed gait maneuvers and finger-tapping tasks (Larson et al., 2007; Martins et al., 2013; Montgomery, 2008). Neurologic “subtle” or “soft” signs such as dysrhythmia and overflow movements, which are unintentional and unnecessary movements that accompany voluntary activity, are often detected. Mirror overflow, for example, includes movements that occur on the opposite side of the body during tasks such as sequential finger-tapping (Cole, Mostofsky, Gidley Larson, Denckla, & Mahone, 2008; Mostofsky, Newschaffer, & Denckla, 2003). Although most basic motor skills are mastered by age 6 or 7, some subtle signs may persist in typically developing children until about age 10 (Larson et al., 2007). However, prominent persistence into late childhood or adolescence may indicate atypical neurological development. These subtle signs are more common in children and adolescents with developmental disabilities, including ADHD, learning disorders, high-functioning ASD, obsessive-compulsive disorder, and Tourette syndrome, and are related to decreased inhibitory control (Cole et al., 2008; Martins et al., 2013; Mostofsky et al., 2003).

Developmental Testing and Neurobehavioral Status Exam

In addition to assessing each stream of development by history, the diagnostician evaluates each child by direct observation and elicitation (Davie, 2012; Leppert, 2011; Montgomery, 2008; Stein & Lukasik, 2009). Formal testing is either completed by the clinician or the results of current testing done by professionals in other disciplines are reviewed or both. Language and nonlanguage/problem-solving aspects of cognition are measured directly. Age-appropriate quantifiable visual-motor measures, such as those that assess figure copying, drawing, and written output, and those that do not require pencil and paper (e.g., block design tasks) are included, and the qualitative aspects of the child’s performance (e.g., pencil grasp, tremor or overflow movements, and qualitative features of the final product) are carefully observed and recorded. In older preschoolers and school-age children, academic achievement is also typically measured using standardized instruments.

Reviews of many of the specific developmental and psychoeducational tests available for assessing children and adolescents are included in Chapter 13 of this volume and elsewhere (Feldman & Messick, 2008; Kral, 2018; Montgomery, 2008; Stein & Lukasik, 2009). In general, physicians who perform independent evaluations tend to use tests that are relatively brief to administer, such as the Capute Scales (CAT/CLAMS; Accardo & Capute, 2005), the Battelle Developmental Inventory (BDI-2; Newborg, 2005), the Mullen Scales of Early Learning (MSEL; Mullen, 1995), the Stanford-Binet Intelligence Scales for Early Childhood (Early SB5; Roid, 2005), the Young Children’s Achievement Test (YCAT; Hresko, Peak, Herron, & Bridges, 2000), the Peabody Picture Vocabulary Test, Fourth Edition (PPVT-4; Dunn & Dunn, 2007), the Kaufman Brief Intelligence Test (KBIT-2; Kaufman & Kaufman, 2004), Raven’s Coloured Progressive Matrices (Raven, Court, & Raven, 1995), and the Wide Range Achievement Test (WRAT-4; Wilkinson & Robertson, 2006). They also use portions or subtests of various measures, such as the Gesell Developmental Schedules (Gesell & Amatruda, 1947; Gesell et al., 1940) and others, to assess different domains of development.

Adaptive functioning is usually quantified using standardized interviews such as the Vineland Adaptive Behavior Scales, Third Edition (Vineland-3; Sparrow, Cicchetti, & Saulnier, 2016) or caregiver-completed rating scales such as the Adaptive Behavior Assessment System (ABAS-3; Harrison & Oakland, 2015), but these may be supplemented by direct observation and elicitation. Criterion-referenced functional measures such as the broad-based Functional Independence Measure for Children (WeeFIM; Msall et al., 1994) and the motor domain-specific Gross Motor Function Classification System (Palisano et al., 2007) are useful for determining an individual’s current ability to perform the tasks of daily living and to fulfill expected social roles. These evaluations can often be used as meaningful outcome measures and to suggest supports necessary for successful progress (Msall & Msall, 2008).

Social behavior is often quantified as part of a broad adaptive measure such as the Vineland-3 or the ABAS-3 but must be directly assessed as well. Appropriate toys should be available to the child so that spontaneous independent play can be observed (often while the clinician is conducting the parent interview) and interactive play can be elicited by the examiner or spontaneously initiated by the child. Eye contact, including referential gaze shifts; response to joint attention bids; and initiation of social communicative interactions, such as bringing/showing toys to the parents to share interest and positive affect, and commenting should

be assessed. Direct assessment measures specific to certain disorders are often utilized when needed to further evaluate clinical suspicion or narrow the differential diagnosis. For example, the appropriate module of the Autism Diagnostic Observation Schedule (Lord et al., 2012) or the standard or high-functioning version of the Childhood Autism Rating Scale (CARS2-ST or CARS2-HF; Schopler, Van Bourgondien, Wellman, & Love, 2010) may be administered (see Chapter 18).

Maladaptive behavior is also typically quantified using standardized rating scales completed by parents or teachers to supplement the history obtained by interview and review of records. The American Academy of Pediatrics Task Force on Mental Health (2010) has published a comprehensive review of available informal tools and standardized instruments, including broad measures (some of which include adaptive behaviors as well) and narrow measures targeting specific disorders or types of symptoms (e.g., ADHD, depression, and conduct problems). Important information can also be gained from qualitative assessment of anxiety, attention, distractibility, impulse control, activity level, compliance, and atypical repetitive behaviors or resistance to change during the interview, testing, and physical examination. Deviations from the norm may be readily apparent upon observation of the child's behavior during the various aspects of the evaluation. It is common, however, not to witness challenging behaviors such as tantrums, self-injury, aggression, and irritability during the evaluation, and even a child with significant ADHD may exhibit few overt symptoms. This does not negate the history provided by the parents, especially when verified by documentation from teachers, therapists, or other family members such as grandparents, since many children are able to temporarily modify their behavior for a few hours, especially in a one-on-one or very small group setting. In contrast, the history is suspect if the child clearly exhibits skills such as appropriate imaginative play and reciprocal social interaction during the evaluation despite parental report that the child never exhibits these behaviors at home or in other settings.

Diagnostic Formulation

Ultimately, the diagnostic process is an exercise in the reduction of uncertainty through information gathering, serial hypothesis generation and testing, and deductive reasoning. The developmental evaluation should culminate in a diagnostic formulation, which in turn guides etiologic investigation and management recommendations. All of the information gathering in the form of the history-taking, record review, and direct

clinical assessment provides the input that the clinician then must compare to existing scientific knowledge of typical and atypical development and behavior to identify the pertinent problems and develop hypotheses to explain these problems in a list called a differential diagnosis.

For over a century, the Oslerian paradigm of formulating a differential diagnosis has been pivotal to best-practice medicine (Pearn, 2011). The differential diagnosis is defined as a list of conditions consistent with the individual's history and observed signs arranged in ranked order of decreasing likelihood. It is constantly modified throughout the evaluation process as additional information becomes available, with potential diagnoses being added, eliminated, and moved up or down on the list. The quality of differential diagnosis depends on clinician history-taking and examination skills, ability to assign relative weights of importance to specific symptoms and signs, and knowledge of disorders of development and behavior and their causes (Pearn, 2011).

The clinician actually formulates and modifies the differential diagnosis throughout the history-taking process. This is further refined by considering the direct clinical assessment; it may be helpful to tabulate the data obtained from the developmental testing, physical examination, and neurobehavioral status examination (Figure 12.3) to facilitate identifying the pertinent problems and narrowing the differential diagnosis through pattern recognition (such as discrepancies suggesting developmental dissociation).

Because developmental disabilities result from diffuse brain dysfunction, the set of problems identified through the thorough evaluation process is likely to include cognitive, motor, and neurobehavioral manifestations and sometimes CNS morphologic anomalies (e.g., microcephaly or structural malformation on brain imaging) or neurophysiologic abnormalities (e.g., seizures, abnormal EEG). This may lead to the tendency to arrive at a long list of diagnoses that is essentially the same list of concerns that the parents had expressed except that it has been translated into medical terminology. Such an approach is not very helpful or very satisfying to parents. Almost 50 years ago, McKusick (1969) used the terms *lumping* and *splitting* to describe two positions on the origin of genetic diseases and emphasized that both had an important place: lumping in connection with pleiotropism ("many from one"—multiple phenotypic features arising from one etiologic factor) and splitting in connection with heterogeneity ("one from many"—the same or almost the same phenotype arising from several different etiologic factors). In developmental disabilities, although splitting is

Domain	Test(s)	Age level	SS or DQ	Grade level	Pertinent qualitative information
Language, verbal IQ					
Problem-solving, nonverbal IQ					
Working memory, processing speed, other					
Visual-motor, fine motor					
Gross motor

Comprehension					
Mathematics					
Writing					
Other academic or pre-academic achievement					
Adaptive behavior					
Social-emotional behavior					
Maladaptive behavior (rating scales)					
General physical exam					
Neurologic exam					
Neurobehavioral status exam					

Figure 12.3. Sample format for tabulating neurodevelopmental assessment data. (Key: DQ, developmental quotient; SS, standard score.)

emphasized in the information-gathering process, etiological diagnosis, and identification of specific impairments to be addressed in treatment, lumping is the key to parsimonious diagnostic classification at the disorder or syndrome level. The diagnostician must emphasize the importance of the forest over the trees.

For example, a particular child may exhibit deficits in language and nonlanguage cognition, self-help skills/activities of daily living, phonology, semantic and pragmatic aspects of language, socialization with peers, reading comprehension, math computation, written output, and motor coordination. The child may also have challenging behaviors including inattention, impulsivity, hyperactivity, tantrums, noncompliance, preference for structure and routine, and perseveration on certain topics or questions. All of these findings can be explained by the single diagnosis of moderate ID rather than a list of diagnoses including moderate ID, ASD, ADHD, GDD, phonological disorder, DCD, and oppositional defiant disorder. Alternatively, the child may be appropriately and meaningfully diagnosed with several categorical disorders (e.g., moderate ID, ASD, and disruptive behavior [e.g., *DSM-5: unspecified disruptive, impulse control, and conduct disorder*]), yet there is likely a single underlying etiology that may or may not be identified through laboratory investigations. Even when a relatively long list of diagnoses is appropriate, it is important to emphasize that the child

has one problem, brain dysfunction, and that these diagnoses represent the most parsimonious description of the manifestations of that brain dysfunction.

Once the diagnostic evaluation has been completed, the diagnoses and recommendations for treatment and further evaluation are presented to the family. Often, referrals are made to specialists in other disciplines, such as special education, speech-language therapy, occupational therapy, or physical therapy (usually within the early intervention or education systems) in order to develop and implement specific treatment plans. In some cases, further evaluation is required to delineate the diagnoses, and referral to a neuropsychologist, clinical psychologist, or speech-language pathologist for additional testing may be necessary.

When explaining the developmental profile and diagnostic formulation to parents, one can start with writing *brain dysfunction* in the center of a blank piece of paper, followed by listing beneath it the child's pertinent problems (impairments), divided into the three categories—*cognitive*, *neuromotor*, and *neurobehavioral*—and sometimes a fourth category, *anatomic/physiologic* (used when there are CNS-related anomalies, such as microcephaly or macrocephaly, or known neurophysiologic abnormalities, such as seizures or an abnormal EEG). Below the three or four parallel columns of impairments, the categorical diagnoses are listed

while explaining the meaning of each. Next, one can go back to the top of the paper and diagram the various causes of brain dysfunction, followed by crossing out those that do not pertain to the child and arriving at those that should be further investigated. This leads to a discussion of recommendations for laboratory tests, imaging studies, and/or other additional evaluations (or brief discussion of why further investigation is not necessary). The potential influence of environmental and experiential influences fits well into the discussion at this point. All of this leads to a piece of paper looking like something similar to Figure 12.4 but specific to the individual. The diagnosis list and profile of impairments can also be referred to during discussion of treatment recommendations.

Etiologic Evaluation

Decision making regarding genetic etiologic evaluation in children with developmental disabilities is informed by a rapidly expanding literature base. Expert recommendations regarding etiologic investigations depend on the specific diagnoses (especially the presence or absence of GDD, ID, or ASD), physical examination findings, neurobehavioral profile, and family history. Less-severe disabilities, such as

language disorders, specific learning disabilities, and ADHD, usually do not require etiologic investigation, such as laboratory or imaging studies, unless the history and/or physical examination suggest the possibility of a specific etiology that requires further evaluation (e.g., vision or hearing impairment, obstructive sleep apnea, thyroid dysfunction, lead toxicity, or physical stigmata of a genetic syndrome). Guidelines pertaining to individuals with GDD, ID, ASD, and CP have been published by organizations including the American College of Medical Genetics and Genomics, the American Academy of Pediatrics, the American Academy of Neurology and Child Neurology Society, the American Academy of Child and Adolescent Psychiatry, the International Standard Cytogenomic Array Consortium (now part of the NIH-funded Clinical Genome Resource [ClinGen]), and others (Ashwal et al., 2004; Manning & Hudgins, 2010; Michelson et al., 2011; Miller et al., 2010; Mithyantha et al., 2017; Moeschler & Shevell, 2014; Muhle et al., 2017; Schaefer, Mendelsohn, & Professional Practice and Guidelines Committee, 2013). Unfortunately, the specific test recommendations tend to become rapidly outdated due to the development of new technology, and the publication of new guidelines may lag several years behind state-of-the-art care.

BOX 12.2 INTERDISCIPLINARY CARE**The Role of the Genetic Counselor**

As professionals who have advanced training in medical genetics and counseling, genetic counselors are an increasingly important part of the interdisciplinary care team for children with developmental disabilities and their families. Traditional roles of genetic counselors include the following (National Society of Genetic Counselors' Definition Task Force, 2006):

- Interpreting family and medical histories to assess the chance of disease occurrence or recurrence
- Educating families, other health care professionals, and the general public about inheritance; genetic testing; management of specific genetic conditions; prevention; research opportunities; and resources for information, advocacy, and support
- Providing counseling to facilitate informed choices and adaptation to a diagnosis or health risk and providing psychosocial support to individuals and families
- Serving as patient advocates, including referring individuals and families to community or state support services

There is consensus that a genetic evaluation should be offered to every person with ID, GDD, and ASD (Muhle et al., 2017), and advances such as the development of chromosomal microarray and next-generation sequencing technologies have led to a substantial increase in the likelihood of obtaining a causal molecular diagnosis (Finucane & Myers, 2016; Retterer et al., 2016; Stessman, Turner, & Eichler, 2016; Vissers et al., 2016). An outcome of more widespread genetic testing and higher diagnostic yield is that there are more individuals and families who would benefit from counseling and education about the implications of their new molecular diagnoses.

As the availability and complexity of genetic tests has increased, pretest counseling and consenting, interpretation of test results, and explanation of the findings (including variants of uncertain significance) to families have become much more complicated. In addition, test results often require reinterpretation over time, including comparison to large genomic data resources because the status of some variants changes as more information becomes available. The expertise of genetic counselors allows them to fulfill these roles, making them invaluable members of the developmental disabilities health care team.

When a specific syndrome or metabolic disorder is suspected based on the history, physical examination, and record review, the next step is to proceed with the appropriate targeted testing or referral to a medical geneticist. In the case of a child presenting with GDD, ID, or ASD, if there is no strong suspicion of a particular diagnosis or testing for suspected diagnoses is negative, a reasonable approach is to pursue CMA and, in most cases, fragile X DNA analysis. If these are unrevealing, whole-exome sequencing (see Chapter 1) should be considered (Muhle et al., 2017; Myers & Challman, 2018). These tests must be explained to families so that they understand the potential benefits and risks as well as the range of potential results (including finding variants of uncertain significance and secondary findings), and involvement of a genetic counselor is highly desirable (see Box 12.2). Some families decline etiologic investigation for various reasons, including concerns about cost or insurance coverage, potential assignment of responsibility or "guilt" to one parent, issues of future insurability of the child, lack of

curative treatment based on etiology, and not wanting to put the child through any discomfort or risk associated with tests. However, most families are interested and find the information to be helpful (Lingen et al., 2016; Reiff et al., 2015).

SUMMARY

- Developmental brain dysfunction, whether genetic or due to other pathology, varies in severity and is manifested as a spectrum/continuum of disorders ranging from high-prevalence, low-severity conditions such as ADHD, learning disabilities, and DCD to low-prevalence, high-severity conditions such as ID and CP.
- Most developmental disorders can have many different causes, and most etiologic diagnoses can result in a variety of different clinical disorders.
- The process of developmental diagnosis includes not only assigning categorical diagnoses, but also

delineating associated deficits, which are typically the primary targets of intervention, quantifying severity, and searching for an underlying etiology.

- The developmental profile compiled during diagnostic evaluation is vital for determining prognosis and guiding treatment planning.

CHAPTER 13

Neuropsychological Assessment

Lauren Kenworthy and Laura Gutermuth Anthony

Upon completion of this chapter, the reader will

- Understand the purpose of neuropsychological assessment
- Be able to describe a model of neuropsychological assessment that incorporates development, brain, and context
- Be familiar with the domains of functioning that neuropsychological assessments address
- Understand how to formulate referral questions and interpret testing results in order to inform treatment
- Know how to maximize the impact of an assessment through effective dissemination of findings and recommendations
- Be able to apply these concepts to a specific case

This chapter focuses on general principles and practical aspects of neuropsychological and cognitive assessment. In order to ensure that the application of this topic is clear, this chapter refers to a specific case about a boy named John throughout (see Case Study, Parts 1–10) to illustrate key points.

■ ■ ■ CASE STUDY, PART 1

John is an 8-year-old boy in the second grade who was referred for a neuropsychological evaluation following difficulties with socialization and schoolwork. He had previously been diagnosed with a sensory integration disorder, motor delay, and anxiety. As a result of this new neuropsychological evaluation, he received a diagnosis of autism spectrum disorder (ASD). John is a boy with

many strengths, including precocious math and science abilities. His parents also report that he has a good sense of humor, likes to learn, and is devoted to a few important people in his life. But he is described as socially isolated, “rude” to his teacher, and inflexible. John also has difficulty producing satisfactory written work.

Thought Questions:

When would standard psychoeducational testing be sufficient, and when would neuropsychological testing be indicated? How might the results of neuropsychological testing be translated into a comprehensive treatment plan, including recommendations for home, school, and therapy?

THE PURPOSE OF NEUROPSYCHOLOGICAL ASSESSMENT

The **neuropsychological assessment** is a valuable tool for determining diagnosis, prognosis, and functional abilities in children (Kaufman, Boxer, & Bilder, 2013). It is particularly important for children with complex environmental, medical, psychiatric, and cognitive factors affecting behavior and learning. Neuropsychological assessment's unique contribution is its ability to provide an integrated understanding of emotional, cognitive, and other factors in an individual child for the purposes of building an effective treatment plan (Braun et al., 2011). See Box 13.1 for a description of the roles of different types of psychologists for children with neurodevelopmental disabilities.

There are currently no medical treatments for the core symptoms of many neurodevelopmental disabilities. For example, primary interventions for intellectual and learning disabilities (ID/LD) and ASD are linguistic, behavioral, and cognitive. In the case of attention-deficit/hyperactivity disorder (ADHD), there are potent medications that target core symptoms, but they are most effective in children when used in combination with behavioral and cognitive interventions (Hinshaw, Arnold, & MTA Cooperative Group, 2015). Because most children with neurodevelopmental disabilities receive school-based services, intervention recommendations that coordinate school, home, and therapeutic settings are a fundamental step to a comprehensive treatment plan (Wolraich & DuPaul, 2010). In addition, there is a great deal of variability within the cognitive profiles of children with neurodevelopmental disabilities. For these two reasons, a neuropsychological evaluation that delineates cognitive strengths and weaknesses and makes specific recommendations regarding classroom placement, accommodations, special education, and therapy can serve as the cornerstone of an effective treatment plan for a child with a neurodevelopmental disability.

Since the 1990s, **neuropsychology** has evolved to better meet the needs of children with neurodevelopmental disabilities. The advent of brain imaging and other sophisticated diagnostic techniques has shifted neuropsychology's role from diagnosis and lesion location to the determination of functional capacities and needs in real-world settings, such as home and school (Burgess et al., 2006; Kenworthy, Yerys, Anthony, & Wallace, 2008; Hardy et al., 2017). Matarazzo (1990) documented this shift in his seminal paper distinguishing *psychological testing*, which is focused on producing test scores, from *psychological assessment*, which incorporates test scores into a broad-based assessment of a person's abilities and environment. Bernstein (2000) elaborated on this in the context of pediatric neuropsychology, saying

"The primary goal of a comprehensive clinical assessment [of a child] is . . . to produce a comfortable, competent 25-year-old" (p. 408), which requires an assessment designed to promote optimum fit between an individual child's cognitive, social, and behavioral profile and the environments in which that child learns and develops (Baron, 2004). This is typically what parents most want from an assessment; however, when evaluations are geared toward the presentation of "test results" or performance on specific criterion-based testing, as within school settings, it is easy for this goal to become lost.

A MODEL FOR DEVELOPMENTAL NEUROPSYCHOLOGICAL ASSESSMENT

The developmental neuropsychological assessment model described by Bernstein (2000) is ideally suited to the needs of children with neurodevelopmental disabilities because it emphasizes identification of diagnostic behavioral clusters or domains, which pose specific risks to the developing child in specific contexts (e.g., elementary school). Bernstein's model of assessment has three key interacting variables: 1) development, 2) brain, and 3) context.

Development is the first key variable. An understanding of development in typical children and in the specific child being assessed is a hallmark of a good assessment. This means knowing that reversing letters when writing is typical in 5 year olds and not expected in 8 year olds, for example. Professionals engaged in assessment must also understand an individual child's developmental trajectory and how a neurodevelopmental disorder may alter brain functions that in turn change the way a child learns and develops other abilities. Piaget (1952) first provided this understanding of children as constructing knowledge through experience. A child's development occurs in the context of his or her own specific brain and environment interacting together. **Joint attention** is a good example of a neurocognitive ability that influences how a child benefits from his or her environment. Joint attention, or the ability to share attention between another person and an object, plays an early developing "self-organizing role" in helping children learn from their social environment (Mundy & Newell, 2007). Impairments in joint attention, as occur in autism, have downstream effects on language, intelligence, and social abilities (Mundy, 2018). Assessment of a developing brain also requires an appreciation of plasticity and consideration of possible brain reorganization following injury. An understanding of the typical course of development, the timing of the insult or injury and its potential effects on brain structure, and the ability to benefit from context are all important (Hunter, Hinkle, & Edidin, 2012; see Case Study, Part 2).

■ ■ ■ CASE STUDY, PART 2

Developmental variables are key to understanding John's neuropsychological profile. The development of his pre-academic skills was precocious. For example, he could recite the alphabet at 18 months of age, demonstrating a facility for memorizing discrete units of information. At 5 years of age, he demonstrated very strong expressive and receptive language skills, and he achieved a superior verbal IQ score. But now, at 8 years of age, John is expected to formulate multiple sentences on a topic of his teacher's choosing, and his precocious vocabulary and verbal memorization skills do not support him on this higher-order academic language task. They do, however, allow him to tell his teacher in very sophisticated language what is wrong with her assignments.

The *brain* is Bernstein's second key variable for assessment. Assessment of a child with a neurodevelopmental disability occurs in the context of an understanding of the neural substrate, or brain structure/function, expected for that disability and observed in the individual child being assessed. It can be very powerful for parents and the treatment team to understand which components of a child's behavior are related to brain-based differences in processing, understanding, and producing information, as opposed to behaviors that may be learned, or even willful, on the child's part. Distinguishing between these two sources of behavior is what helps parents distinguish when a child "can't"—as opposed to "won't"—do what they expect (Kenworthy et al., 2014). In the case of "can't," parents and treatment teams can clearly understand that changes in the demand or context will be needed (see Case Study, Part 3). For example, most children with ADHD and ASD struggle with executive dysfunction, especially disorganization. Many of them cannot sit down on their own initiative at home to begin homework, but if the context is altered to be more supportive, through the provision of a written schedule, checklist, breaks, and rewards, they are successful.

■ ■ ■ CASE STUDY, PART 3

By learning about John's brain-based deficits in executive function, in particular his disorganization and inflexibility, his teacher was able to understand that this bright boy with an oversized vocabulary really *couldn't* organize words into written responses on specific topics of her choosing *unless* he was taught a highly structured writing rubric. Like many of us, until instructed otherwise, she assumed that a boy with John's core language abilities and considerable intelligence must be *choosing* not to write.

This leads directly to the final key variable in assessment, the *context* within which the child develops (see Figure 13.1) and is performing. Context is defined by Bernstein to include all aspects of a child's environment, and it is important for many reasons. It is essential to understand how a child's context and history may affect his or her performance during an assessment. For example, impaired vocabulary in a 7-year-old child who comes from a home in which books are read to him daily raises concerns regarding possible abnormalities in left frontal-temporal brain networks and suggests the need for specialized therapy. The same vocabulary in a child whose family speaks a language different from that in which the assessment was administered may simply indicate a familial and cultural basis for the vocabulary deficit and the need for increased exposure to English. The context of the assessment itself is vital as well. The 7-year-old child with impaired vocabulary may be reacting poorly to the assessment setting. Perhaps the examiner was unable to develop adequate rapport with the child, who became very anxious and provided only minimal responses. Many children behave differently in school, home, and clinical settings, and thus information must be gathered about performance in each setting to create a complete picture. Finally, an understanding of future contexts is important for an assessment to effectively predict risk and make recommendations. For example, a 4-year-old child with impaired phonological awareness and poor ability to break words down into individual sounds may be thriving in a nonacademic preschool but is at great

Figure 13.1. Viewing the child in context.

risk of failure in a kindergarten setting where reading skills are emphasized. Likewise, a very bright but disorganized fifth grader is at great risk for increased difficulties when he or she makes the transition to middle school with its demands for managing multiple subjects, teachers, and longer assignments. Delineation of risks is what drives practical recommendations for intervention. Development, and successful recommendations for enhancing development, do not exist in a vacuum. They occur within specific settings that can affect the course and prognosis of a child's difficulties, the way these difficulties are expressed, and the success of treatment. For this reason, *tests should not be used or interpreted in isolation* (see Case Study, Part 4).

■ ■ ■ CASE STUDY, PART 4

In John's case, consideration of context was important for many reasons. For example, although his parents were concerned about his lack of social skills, John had a close friend his age who did not have any neurodevelopmental disabilities. He saw his friend frequently, and his ability to sustain this friendship raised questions about whether he had greater social interaction abilities than his parents gave him credit for. Review of the context revealed, however, that this friend was a member of a family that socialized with John's whole family on a regular basis, and so John was not sustaining the friendship independently, but rather benefitted from a highly supported social context.

Assessment requires the integration of 1) test performance, behavioral observations, and contextual information provided by parents, teachers, and treatment team; 2) principles of development; and 3) knowledge of brain function. This information is integrated across the span of the child's development and across the settings the child inhabits. Baron (2004) terms this process *convergence profile analysis*, highlighting the fact that one test score or reported behavior is insufficient to generate an accurate cognitive profile. For example, take an assessment designed to answer whether or not a child has an attention deficit. All of the following questions must be answered before a determination can be made:

1. Is there a history of problems paying attention, or is it a new problem?
2. Is the child inattentive to all types of stimuli (people, words, and pictures) or just some types?
3. Is the child inattentive at home, at school, and in the clinician's office, or just in some settings?

4. What are the demands being placed on the child to pay attention, and what attention demands will he or she confront in the future?
5. What other cognitive, emotional, or contextual factors are affecting the child's ability to pay attention?
6. Have medical sources of attention problems, such as sleep disturbance and thyroid abnormalities, been ruled out?

A comprehensive neuropsychological assessment should provide a thorough investigation of each of the domains of functioning that are described in the next section of this chapter. The goal is to delineate a pattern of cognitive and behavioral strengths and weaknesses, to identify the risks posed by a child's profile in the contexts he or she inhabits, and to generate recommendations to ameliorate those risks through accommodations, special education, and therapy (see Case Study, Part 5).

■ ■ ■ CASE STUDY, PART 5

Convergence profile analyses were essential for interpreting John's attention data. His parents reported that John had considerable difficulty maintaining focused attention at home, but he performed well on a computerized attention task during the assessment. His attention to the examiner's spoken directions was somewhat less consistent, but he usually knew exactly what to do before she had finished giving directions anyway. He was least attentive in the assessment when the examiner tried to chat with him about her own interests and experiences. His teacher reported that John had problems attending to instructions, to class discussion, and to tasks that he found boring, but she also reported that he had excellent focus once he was engaged in independent work on a task that interested him. John also experienced problems with generalized anxiety, which contributed to difficulty falling asleep. Integrating these data across contexts and tasks suggests that John does not have a pervasive problem with attention, but rather has increasing difficulty attending as the context becomes less structured and predictable, as the demands on executive function increase (home versus school), and as the social content of the material increases (e.g., having good attention to a computerized task or in independent work but poor attention when people are talking to him). This points to executive and social deficits as the primary problem, not attention. John's remarkable intelligence is another key factor affecting attention, as he typically understands information very quickly and thus is more easily bored. Finally, his sleep problems and anxiety may contribute to John's attention problems, a finding that has important implications for treatment strategies.

BOX 13.1 INTERDISCIPLINARY CARE**The Varieties of Psychology**

What are the differences among a neuropsychologist, a clinical child psychologist, and a school psychologist? The American Psychological Association (2012) defines the three specialties this way:

1. Clinical neuropsychology is a specialty in professional psychology that applies principles of assessment and intervention based upon the scientific study of human behavior as it relates to normal and abnormal functioning of the central nervous system. The specialty is dedicated to enhancing the understanding of brain–behavior relationships and the application of such knowledge to human problems. A pediatric neuropsychologist is a specialist within clinical neuropsychology who addresses these considerations in infants, children, adolescents, and emerging adults.
2. Clinical child psychology is a specialty in professional psychology that develops and applies scientific knowledge to the delivery of psychological services to infants, toddlers, children, and adolescents within their social context. Of particular importance to the specialty of clinical child psychology is an understanding of developmental models and their relationships with the basic psychological needs of children and adolescents, as well as how the family and other social contexts influence the socio-emotional adjustment, cognitive development, behavioral adaptation, and health status of children and adolescents.
3. School psychology is a health service provider specialty within professional psychology that is concerned with the science and practice of psychology with children, youth, and families; learners of all ages; and the schooling process. The basic education and training of school psychologists prepare them to provide a range of psychological diagnosis, assessment, intervention, prevention, health promotion, and program development and evaluation services with a special focus on the developmental processes of children and youth within the context of schools and other educational systems.

Practically speaking, there is a fair amount of overlap, and most neuropsychologists are trained in either clinical or school psychology programs with specialized coursework and training. It could happen that a child like John could see all three types of psychologists, either at the same time as part of a multidisciplinary team or consecutively as new or different assessment questions emerge. For example, John's neuropsychologist might evaluate how his developmental brain differences impact his everyday functioning; John's clinical psychologist could assess for other mental health issues, such as his anxiety or sleep problems, or lead his treatment team after diagnosis; and John's school psychologist could be instrumental in setting up a successful program of adaptations and interventions in school to help him be a successful student. Alternatively, John could be assessed and treated by only one of these professional subspecialties.

DOMAINS OF FUNCTIONING ASSESSED IN NEUROPSYCHOLOGICAL EVALUATIONS

A comprehensive neuropsychological assessment includes a description of strengths and weaknesses. For each neuropsychological domain, the assessment should provide a clear summary statement describing the child's abilities and an integration of data from multiple sources. A full assessment includes multiple methods—for example, parent and child clinical interviews and/or structured standardized interviews such as the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2; Lord, Rutter, DiLavore, & Risi, 2012) and the Autism Diagnostic Interview, Revised (ADI-R;

Rutter, Le Couteur & Lord, 2003); norm-referenced rating scales from the parent, teacher, and child (self-report); behavioral observations; standardized, norm-referenced tests in relevant domains; and sometimes supplemental subjective measures (see Box 13.2). Although the specific neuropsychological domains and their labels can vary somewhat depending on the examiner, the most commonly referenced domains of functioning are defined below. Table 13.1 also lists these domains, indicates neurodevelopmental disabilities that may be associated with deficits in each domain, and gives examples of relevant data sources regarding each domain. There is also a table listing many common tests associated with each of these domains in the appendix at the end of this chapter (see Appendix 13.1).

BOX 13.2 EVIDENCE-BASED PRACTICE**Focused Models of Assessment**

- In the field of pediatric neuropsychology, the norm had been to conduct a comprehensive, 1–2 day evaluation that sampled all domains of functioning; however, many professionals now are emphasizing the importance of a focused battery. Youngstrom (2013) argues that an evidence-based assessment is targeted and parsimonious: Specific, clinically relevant questions are addressed with the briefest, most focused evaluation possible. Thus, if a child has a specific problem or a simple diagnostic question (e.g., whether he or she has attention-deficit/hyperactivity disorder) a comprehensive neuropsychological assessment may be an inefficient use of time and money. Conversely, a child who is having trouble making friends and struggles with anxiety, emotional outbursts, and writing and reading at school may need a comprehensive evaluation in order to inform differential diagnoses and investigate possible weaknesses across many domains of functioning.
- One downside of comprehensive evaluations is the time required to produce and read the reports they generate. A recent survey of neuropsychologists and their referral sources revealed that many neuropsychologists do not believe that the reports they write are read in their entirety and that 73% of referral sources feel that slow turnaround time of reports negatively affects their patients' care. The components of neuropsychological reports that they found most helpful are the diagnosis, impression, and recommendations sections (Postal et al., 2018).
- Models for triaging assessment referrals and customizing assessment protocols and reports are increasingly important to make sure that the referral questions are answered efficiently. Hardy and colleagues (2017) have elaborated a graduated system of evaluation with three tiers of assessment for children with medical conditions affecting the central nervous system:
 1. Universal monitoring by the medical treatment team (with brief questionnaires or computerized tasks)
 2. Targeted screening by the neuropsychologist for those children with greatest risk or who are identified to be at risk through monitoring
 3. Comprehensive evaluation for those for whom screening is inadequate to address concerns

General Intelligence

General intelligence is commonly discussed in neuropsychological assessments and is often considered the benchmark against which other cognitive abilities are measured. For example, a child with an overall IQ score that is in the intellectually deficient range would not be identified as having a specific visual processing deficit unless difficulties in that domain were greater than what would be expected based on his or her IQ. Yet, it is important to recognize that general intelligence scores have narrower implications for a child's ability to become a successful and happy 25 year old than is often assumed by parents. Intelligence testing originated in early 20th-century France as a method to predict which children would succeed in school. Its development in 20th-century America included the delineation of separate factors in intelligence with a strong emphasis on verbal knowledge and spatial performance as key factors in determining overall intellectual abilities.

Crystallized intelligence (using knowledge and experience) versus **fluid intelligence** (solving novel problems) is another common dichotomy. Processing speed has played an increasing role in our understanding of performance on IQ tests, particularly in children with congenital or acquired brain abnormalities (see Donders & Strong, 2015). In any case, Gardner's (1983) seminal book on multiple intelligences serves as an important reminder that IQ scores capture only a fraction of the many abilities that govern a person's performance in the real world. Other caveats regarding measures of general intelligence are that 1) crystallized and verbal knowledge measures are affected by the home and school environment, 2) IQ scores are unstable in young children and are not necessarily predictive of later performance on intelligence tests, and 3) the causes of poor performance have been oversimplified. For example, Wechsler Processing Speed Index scores are heavily reliant on fast processing but also on fast motor output, a demand that is not recognized by their name.

Table 13.1 Common neurocognitive domains and associated neurodevelopmental disorders

Domain	Examples of associated neurodevelopmental disorders	Examples of key data sources
General intelligence	Intellectual disability	Standardized IQ tests
Attention	Attention-deficit disorder Emotional disorders (anxiety, depression, trauma) Traumatic brain injury Epilepsy	Parent and teacher rating scales and qualitative report Observations during assessment Standardized tests
Executive function	Attention-deficit disorder Autism Reading disability Prematurity Nonverbal learning disability Traumatic brain injury	Parent and teacher rating scales and qualitative report Observations during assessment Standardized tests
Language	Language-based learning disabilities (reading, writing) Developmental language disorders Autism Hearing impairment	Observations during assessment Standardized tests School work Qualitative parent and teacher report
Visual perceptual	Nonverbal learning disability Prematurity Visual impairment	Standardized tests Observations during assessment
Learning/memory	Autism Attention-deficit disorder Learning disabilities Developmental language disorders Nonverbal learning disability Traumatic brain injury Intellectual disability Epilepsy	Standardized tests Observations during assessment Qualitative parent and teacher report
Social cognition	Autism Nonverbal learning disability	Parent and teacher rating scales and qualitative report Structured interview observations Standardized tasks
Motor/sensory	Cerebral palsy Attention-deficit/hyperactivity disorder Autism Nonverbal learning disability	Standardized tests Observations during assessment Work samples
Emotional adjustment	Depression Anxiety disorder Trauma Adjustment problems Bipolar disorder Attention-deficit disorder Medical disorders	Parent and teacher rating scales and qualitative report Observations and self-report during assessment Projective measures
Adaptive/academic	All	Parent and teacher qualitative report and report on standardized adaptive behavior interviews Standardized academic tests/tasks Work samples

The Wechsler Arithmetic subtest requires listening to a word problem and then performing arithmetic operations without paper to produce an answer. As a result, the task includes auditory processing (listening to the

question), verbal processing (identifying the quantities and operations required), working memory (maintaining the key elements in working memory and performing operations on them), and exposure to arithmetic.

Attention

Attention is closely associated with, and sometimes even subsumed under, executive function. Common subdomains within the concept of attention include orienting, focusing, shifting, and sustaining attention. Attention relies on complex distributed networks in the brain (Mesulam, 2000; Posner, 2016). Attention is affected by a diverse array of factors including anxiety, arousal (most sleepy people are inattentive), difficulty of the task (e.g., dyslexic children are inattentive specifically on reading-related tasks), motivation (e.g., interest level in the material), and the novelty, as well as the type, of the situation. A finding of impaired attention should be based on data showing difficulty paying attention in several different contexts (home and school), on a variety of tasks, and in the absence of other interfering mental states.

Executive Function

Executive function is an umbrella term that captures a set of cognitive abilities that governs behavior regulation and goal-oriented activity. These cognitive processes include working memory, inhibition, flexibility, monitoring, planning, and generativity (Rogers & Benvenuto, 2000). Executive functions rely on complex interconnected brain networks emphasizing frontal and subcortical nodes (Hunter et al., 2012; Stuss & Benson, 1984). Executive functions are notoriously difficult to capture in the standard test-based assessment, as the assessments are usually conducted in a quiet room with one highly supportive adult examiner prompting performance. In this structured environment, the examiner 1) provides the plan, 2) organizes the activities, 3) gives explicit instructions and cues regarding performance, 4) probes for elaboration, 5) presents tasks one at a time, and 6) generally supports executive control (Gioia, Isquith, Guy, & Kenworthy, 2015). Such support makes it difficult to reveal deficits in this area and, in fact, is the approach a teacher takes to assist a child with executive function deficits. Therefore, intact performance on an executive function test should not be considered adequate evidence of intact executive function. Often some subdomains of executive function are intact while others are impaired in a child with a neurodevelopmental disability. By school age, delineation of performance in specific subdomains (e.g., inhibition/impulse control versus planning or self-monitoring) is informative for targeting specific interventions (e.g., interventions to support and improve weak working memory are quite

different than those targeting impulse control or flexibility; see Case Study, Part 6).

■ ■ ■ CASE STUDY, PART 6

John, like many children with high-functioning ASD, had specific executive function deficits affecting his ability to organize, integrate, and plan using complex information or multistep tasks, which affected his ability to write essays at school. He required targeted interventions to help him learn to use a specific writing rubric that provided familiarity and structure to this otherwise open-ended, overwhelming task. John also struggled with cognitive inflexibility and needed to learn routines and scripts to help him be more flexible. On the other hand, John's ability to manipulate numbers in working memory was remarkable, and he generally had adequate impulse control.

Language

This domain addresses the ability to understand language, use language to express needs and wants, establish social relationships, and make the sounds of speech (see Chapter 17). Often subsumed under the language domain are a full range of communicative abilities, including motor speech capacities and pragmatic non-verbal communications such as gestures. At its core, the language domain involves the phonological, semantic, syntactic, and formulation abilities that enable us to distinguish and combine sounds, build a vocabulary, and combine words into sentences and longer utterances. Language abilities rely heavily on frontotemporal brain networks, typically in the left hemisphere (Bear & Connors, 2016). Language skills are often divided between receptive or comprehension abilities and expressive abilities, which can be divergent. Although most neurocognitive evaluations screen basic language abilities and can be helpful in differentiating the unique contributions of attention, executive function, social cognition, and language difficulties to a problem in the child's functioning, a significant concern regarding language abilities typically also merits a full speech and language assessment (see Case Study, Part 7).

■ ■ ■ CASE STUDY, PART 7

John's basic language abilities related to phonology, semantics, and syntax were very strong and supported fluent reading, decoding, excellent vocabulary, and a sophisticated use and understanding of words and sentence syntax. His communication deteriorated, however, as executive demands to organize and integrate information

into paragraphs or as pragmatic language demands to use gestures and eye contact increased. Finally, inflexibility drove him to be overly precise in his use of language and interfered with his ability to maintain a conversation about topics that were not intrinsically interesting to him.

Visual Processing

The brain supports a variety of visual processing abilities, including perception and spatial location. Right hemisphere posterior brain structures are frequently involved, although the neural underpinnings of visual processing are complex (see Baron, 2004, for review). Visual processing is closely associated with visual construction skills, which also require motor output; perception of visual gestalts; and visual pattern recognition, often associated with visual reasoning. All of these skills rely on intact or corrected vision. Isolated deficits in this domain are not common in neurodevelopmental disabilities, and it is important to recognize that a significantly lower Wechsler Performance IQ score than Verbal IQ score cannot be interpreted in isolation to indicate a perceptual deficit (see Case Study, Part 8). Such a discrepancy can result from many different conditions, including executive dysfunction and highly enriched verbal teaching at home and at school. A true deficit in this domain should be confirmed with performance data other than IQ scores, such as scores on tests of visual learning and memory.

■ ■ ■ CASE STUDY, PART 8

John's IQ scores showed a significant discrepancy between very superior Verbal IQ and average Performance IQ. Yet, he is a gifted math student and has strong visual learning abilities. Observation of John's approach to the tasks that constitute the Performance IQ revealed that his inflexibility and tendency to focus on details slowed his performance and reduced his score, implicating executive dysfunction, not a perceptual deficit.

Learning and Memory

Although true memory impairments are relatively rare in children with neurodevelopmental disabilities, learning deficits are common. Learning can be impaired for visual or verbal information in the context of core deficits in language or visual processing. Executive dysfunction also typically interferes with effective information retrieval in response to open-ended queries (e.g., "How was your day?") and with learning large amounts of information but not with information

retrieval in structured conditions (e.g., multiple choice) or when learning simpler data. A neuropsychological evaluation should provide specific insights into how a child learns best and in which learning conditions the child will require extra support (e.g., only during lectures, written responses, or independent reading). Optimizing learning is a key intervention for all children since their major academic task is to learn new information (see Case Study, Part 9).

■ ■ ■ CASE STUDY, PART 9

In John's case, it was useful to delineate the difference between his prodigious learning and memory abilities for small chunks of information such as words, facts, and mathematic operations and his much greater difficulty with learning and retrieving large chunks of information from memory. In the assessment, he struggled with learning and remembering a large, complex abstract figure; in his daily life, he struggled to learn from his experiences.

Social Cognition

Social perception and cognition rely on fronto-temporal brain networks that support a person's ability to perceive social stimuli such as faces, facial expressions, voice intonation, and body language. The brain also "reasons" using social information, such as understanding human relationships and having a theory of mind; this social reasoning ability is commonly referred to as social cognition (for reviews, see Frith & Frith, 2010). However, our ability to measure social cognition with standardized tools is still quite limited. With the exception of basic social perception tasks (such as learning and remembering faces and recognizing facial expressions), measuring social cognition largely relies on parent and teacher report, observation, and responses in structured interviews. For planning successful interventions, it is essential to have an understanding of whether a child with a neurodevelopmental disability can accurately perceive and express social cues, have a theory of mind, and reason with social information.

Motor/Sensory

The motor and sensory domains encompass a broad range of gross and fine motor abilities as well as sensory perception. Standardized motor tasks eliciting speed, strength, and dexterity, such as quickly placing pegs in a board, tracing a curvy line, or imitating a gait or hand movement, can provide information about the subtle motor impairments often seen in neurodevelopmental

disabilities. These impairments can profoundly affect a child's ability to produce written work at school, to carry out key activities of daily living, or to simply sit up straight in his or her chair. A complex or pervasive motor difficulty often merits a physical or occupational therapy evaluation. Sensory information regarding visual, auditory, and tactile perception can also be collected with standardized assessments and can be particularly important for children with focal brain damage. Oversensitivity and undersensitivity to sensory stimuli are included in the diagnostic criteria for autism (American Psychiatric Association, 2013) and are best assessed by observation and parent or teacher report.

Emotional Adjustment

Emotional adjustment should be evaluated in any comprehensive assessment because it has a major impact on a child's overall functioning level, the intervention plan, and specific neurocognitive functions. Mood, anxiety, and any other emotional difficulties interfering with a child's functioning and ability to regulate mood and behavior should all be assessed. These data may inform diagnosis of comorbid psychiatric disorders. They may also indicate alternative explanations for cognitive impairments. For example, working memory can be impaired by anxiety (Ferreri, Lapp & Peretti, 2011); depression slows down motor response and generally impairs performance on tasks requiring cognitive effort (Buyukdura, McClintock, & Croarkin, 2011); and even hallucinations occur in a small number of children, which certainly interfere with attention (Castaneda et al., 2008). Parent, teacher, and child reports on standardized measures, as well as a qualitative report of symptoms and concerns, are useful. In addition to an interview with the child, which can be play based for younger children, the child's response to projective measures is often informative. Projective measures present incomplete or ambiguous stimuli (such as drawings, sentence beginnings, or inkblots) and are designed to elicit information about the child's internal state.

Adaptive/Academic

Adaptive and academic skills are best thought of as outcomes of the pattern of strengths and weaknesses in a child's core cognitive domains, combined with the full range of contextual factors described above. They reflect how successfully the child is coping with the demands of daily living (e.g., showing age-appropriate toileting, dressing, grooming, communication, and social skills) and accumulating academic knowledge and skills.

ENSURING THAT ASSESSMENT INFORMS MANAGEMENT

Useful Assessments Are Driven by Appropriate Referral Questions

Neuropsychological assessment can answer or provide input on a wide range of questions, but there are at least as many questions that it cannot, or should not, answer. A comprehensive neuropsychological assessment can often provide input in the following areas: 1) diagnostic clarification, 2) the child's level of developmental or cognitive functioning, 3) patterns of strengths and weaknesses, 4) school placement or program eligibility determinations, 5) progress or deterioration over time, 6) forensic issues, and 7) suggestions for treatment. Assessment can rarely definitively answer questions such as "What caused this to happen?"

A good referral request asks a clear, answerable question. Some examples of appropriate questions would be whether a child has ASD, whether a child's difficulties are due to language or attention problems, or whether a child is receiving appropriate services and making the expected level of progress. Providing the evaluator with information about the strengths and weaknesses of the child, the family system, and the current educational plan will increase the utility of the assessment. Specifying which exact tests should be given is not useful. There may be very good reasons for not giving a certain test, such as any of the threats to validity described below.

An Understanding of the Purpose and Limits of Psychometric Data Informs Effective Use of Assessment Results

When selected, administered, and scored appropriately, standardized test instruments provide important normative benchmarks against which to compare performance. They complement nonstandardized data and provide key information about how a child's abilities compare with same-age typically developing children. One study (Meyer et al., 2001) compared psychological tests with medical tests like magnetic resonance imaging, Pap smears, and electrocardiograms and found that psychological tests generally predict outcomes just as well as medical tests do.

The term *psychometrics* refers to the branch of psychology addressing the design, administration, and interpretation of quantitative (numerical) tests that measure psychological factors such as intelligence, aptitude, and personality traits (Upton & Cook, 2008). Psychometric approaches have proven to be extraordinarily useful over time but have been criticized for

being overly reductionistic (tending to oversimplify complex phenomena by breaking them down into constituent parts). Because of the inherent limitations of the psychometric approach, professionals are often required to meet standards for training and experience in order to be able to purchase psychological tests and to be licensed to administer and interpret those tests (American Educational Research Association, American Psychological Association, National Council of Measurements in Education, & Joint Committee on Standards for Educational and Psychological Testing, 2014). This sets a very high standard for the appropriate interpretation of any test score and should caution unqualified people against attempting to interpret scores.

Psychometric measures should be interpreted with caution for many reasons. Psychometrics do not model the neural substrate (e.g., a test score does not map neatly onto brain regions or functions) or place behavior in context. Further, psychological tests are rarely pure (e.g., they do not measure only the domain they are supposed to measure), are not completely objective (e.g., variability in examiners or cultural factors can have a significant impact on scores), and are not always reliable and even less often valid. The results of any psychometric measure are only as good as the measure itself. The largest factors that contribute to score accuracy include 1) the use of standardized procedures; 2) the reliability of the test; 3) the validity of the test; and 4) the quality, size, recency, and diversity of the normative sample. Described below are some of the most important psychometric factors a neuropsychologist considers.

What Does It Mean for a Test to Be Standardized?

A test is standardized if 1) it has exact procedures for administration, including the qualifications of the administrator; 2) it has instructions and questions that must be repeated in exactly the same way every time (i.e., the administrator must “stick to the script”), 3) the exact same materials are used every time; and 4) rules for scoring are specifically defined and are not subjective (Sattler, 2018).

What Does It Mean for a Test to Be Reliable?

Reliability is a measure of how consistent a score is over time (test-retest reliability), between examiners (interrater reliability), across different forms of the test (alternate forms reliability), and within the items of the test (internal consistency). Reliability can be affected by the length of the test, variability in the normative sample, the difficulty range of the items (it is important that items are neither too difficult nor too easy), and

how well the administration and scoring procedures are described.

Reliable change refers to the extent to which the change in an individual's scores fall beyond the range that could be attributed to the measurement variability of the instrument or the effects of practice. Many new standardized assessment tools often provide Reliable Change Index scores.

What Does It Mean for a Test to Be Valid (and What About Bilingualism, Culture, Race, Ethnicity, and Income Levels)?

A test is valid if it accurately measures what it is supposed to measure. A well-standardized test has undergone many different types of checks for validity under controlled situations. However, most tests are used outside of these controlled situations, and therefore the evaluator should tell the reader of the report how valid he or she believes a child's assessment to be and how predictive the assessment is likely to be of that child's functioning. For instance, most individually administered tests (such as IQ tests) are not valid if repeated within 6–12 months because practicing the tasks improves performance on those tasks. Child-specific factors can also reduce the validity of a test result. Was the child hungry, tired, ill, or distracted? Was the child taking any medication that could affect results? Cultural factors should always be considered as a potential threat to validity; a test's questions may contain content and assume knowledge that are foreign to the child's environment. For example, a child from Taiwan may not be able to correctly categorize the fruits we typically eat in the United States. Poor performance in this case relates to the child's culture, not to her categorization or abstract thinking ability. But we also know that no test is without biases, which may be more subtle and may disproportionately identify children from “nondominant” cultures for some categories of special education services or contribute to the underidentification of children for gifted services (Voulgarides, Fergus, & Thorius, 2017). In the United States this is a particular problem with testing of African American and Hispanic populations and contributes to educational disparities (see Chapter 42).

Sometimes a certain child will need accommodations during testing or will need to be given special tests, and the report should acknowledge these factors and how they affect validity. A child with cerebral palsy (CP) or other physical disabilities may need to be given motor-free tests, and even verbal tests should not be timed. When a child with a language disorder is assessed in other domains, nonverbal tests should be given (such as the Leiter or the Comprehensive Test of Non-Verbal Intelligence). A child who speaks

a different language should either receive culturally appropriate nonverbal tests or a test that has been carefully translated, adapted, and standardized in the child's native language and culture; bilingual children should receive some testing in both of their languages (Sanchez et al., 2013). Some testing accommodations are less dramatic, such as allowing the child to stand or move around the room, instituting reward systems, and breaking the testing up into several sessions. But these accommodations should be noted in the report, as the validity of the findings may be tied to them. This can also be helpful in alerting teachers and parents to specific accommodations that are likely to improve performance at home and at school.

The validity of tests can also be challenged by intentional efforts on the part of the person being assessed to make mistakes or "malingering." A formal assessment of effort, using embedded or standalone "symptom validity" tests, is an important component of evidence-based practice in neuropsychological assessment (Greve, Durtis, & Bianchini, 2013). Effort testing should be included in most assessments. Performance on these tasks should be noted in a section of the neuropsychological report that addresses the validity of the assessment.

Why Is It Important for a Test to Be Norm-Referenced?

A test is norm-referenced if it has been given to a large number of people (the sample) who are representative of the population of interest. An individual child's performance is measured against the performance of all children of the same age in the normative sample in order to generate a standard score. The larger and more diverse the normative sample is,

the more useful this standard score is. Cultural, linguistic, and physical factors that the child does not share with the normative sample will reduce its utility. The normative sample also must be recent, as children's scores in the population change over time. For example, cognitive intelligence scores have been shown to increase by about three standard score points per decade (Trahan, Stuebing, Hiscock, & Fletcher, 2014).

What Is a Standardized Score? Standardized scores are statistically derived from the normative sample during test development. All standardized scores assume that the scores range according to a normal distribution (see Figure 13.2). There are several types of standardized scores. Test scores can be expressed as follows:

1. *Age or grade equivalents.* Performance is typical of a specific age group or grade level in the normative sample. While age and grade equivalents are the most intuitive of the standardized scores and are the most easily understood by parents and teachers, they should not be used for making diagnostic or placement decisions because of their low reliability and validity (American Educational Research Association et al., 2014).
2. *Percentiles.* This ranks the child's relative position in the normative sample. For example, a child's score at the 80th percentile means that the child performed better than 80% of children in the sample.
3. *Deviation scores.* The child's performance is assessed in relation to the distance from the mean in terms of standard deviations (SD). The SD of a score is a

Figure 13.2. The normal curve.

measure of how much variability there is in scores in terms of distance from the mean (average). Standard scores, scale scores, *t*-scores, and *z*-scores are all deviation scores. Standard scores typically have a mean of 100 and an SD of 15. Scale scores typically have a mean of 10 and an SD of 3. *T*-scores have a mean of 50 and an SD of 10, and *z*-scores have a mean of 0 and an SD of 1.

Most children (about 68%) obtain scores within 1 SD of the mean. These scores are considered “average.” The further a score is away from the mean, the fewer children obtain that score. Figure 13.2 represents what is commonly referred to as the “Bell curve” or the normal distribution of scores in a group of individuals. The area under the curve represents the number of children obtaining that score. If Figure 13.2 represents a total of 1,000 children, then 680 children would obtain scores in the area of the curve representing the “average range.” However, only one child would obtain a score in the small area under the curve in the “very superior range,” which is the area of the curve 4 SDs above the mean. The general labels used to describe scores are depicted in Figure 13.2, but each test may also use its own descriptive labels depending on what the test is measuring. For example, a child who scores very low on an anxiety measure, such as a *t*-score of 20, is not said to be “deficient” of anxiety symptoms. Instead, a *t*-score of 70 on the anxiety measure may be described as “clinically significant,” meaning that the score indicates noteworthy anxiety symptoms.

Interpreting the clinical significance of variability between scores often requires more than simply understanding the standardized score itself. It is important to recognize, for example, that intra-individual variability in standardized scores on different tests is expected, especially in children (Schretlen & Sullivan, 2013). A good assessment takes into account expected variability and only reports “strengths” and “weaknesses” on tasks with scores that are more discrepant than is typical for that measure.

Effective Feedback and Dissemination of Findings

A meta-analysis (Poston & Hanson, 2010) showed that when psychological assessment and the sharing of assessment results is done in a collaborative fashion with the child and his/her family and the feedback is offered in a sensitive, clinically meaningful manner, the assessment process itself functions as a therapeutic intervention. Effective communication of assessment results is essential for optimizing the power of an assessment as an intervention tool. When a child

is referred for a medical specialist’s consultation, the professional making the referral wants the specialist’s interpretation and integration of information to answer the referral question and to suggest avenues of treatment, if needed. The same is true of referrals for neuropsychological assessments. Presentation of cognitive strengths and weaknesses, appropriate diagnoses, primary risks, and recommendations should all be communicated in a collaborative conversation and in language that both the referring professional and the parents can understand. One important way to make sure that test results are clear is to describe all test scores in a consistent, clearly explained manner. Increased standardization in the reporting of test data with standardized qualitative descriptors for normalized test scores (e.g., “average” or “superior”) is an evidence-based practice (Schoenberg & Rum, 2017). Many reports describe test performance in multiple ways, which is needlessly confusing.

An assessment’s value is determined by its usefulness and intelligibility to the family and education/treatment team of the child being assessed. Standards of care include offering in-person feedback regarding the findings of an evaluation, providing recommendations for an effective treatment plan, and writing a report that serves as a document that parents and referral sources can share with schools, members of the treatment team, and others who may intervene on behalf of the child. It is essential that the written report is completed in a timely manner and that the diagnostic formulation, impression, and recommendation sections of the report are clearly written and accessible to the reader, as these are the most commonly read portions of neuropsychological reports (Postal et al., 2018).

Often the most important intervention resulting from an assessment is simply to see the child’s behavior in a new light. For example, a child who is described by his teacher as unmotivated can now be seen as a child with short-term memory problems, an attention disorder, or depression. This reframing of the problem can lead teachers, parents, and other adults to change their intervention strategies and to modify their interactions with and expectations of the child. This in turn can lead to a difference in how the child sees himself/herself. The first step in this reframing process is to confirm that the parents understand the assessment results. Follow-up questions regarding what was communicated during the assessment feedback session are important because misunderstandings are common. Provision of resources that will help the family move toward a greater understanding of their child’s strengths, weaknesses, risks, needed interventions and accommodations, and prognosis may enable parents to be their child’s best advocate.

Implementation of Recommendations

The next step is to make sure that a plan is in place so that all necessary recommendations can be implemented. This can be an overwhelming process for parents, particularly if their child needs multiple types of interventions and accommodations. It is important to help parents recognize that many assessments provide recommendations meant to be implemented over a period of several years. Prioritizing among recommendations and identifying key initial targets for intervention can be helpful. Referral sources often assist families in this process; they report that the diagnosis, impression, and recommendations sections of neuropsychological reports are especially valuable in supporting their efforts to help families (Postal et al., 2018). Very often, recommendations will call for changes in both school-based and home/outpatient-based services (see Case Study, Part 10).

■ ■ ■ CASE STUDY, PART 10

John's assessment report led to several significant changes. Perhaps most important, his parents and teachers became better able to distinguish his "can'ts" from his "won'ts." He was provided with some social coaching to help him read social cues and understand how his behavior can seem rude to others. An individualized education program (IEP) was established in school, which allowed him to use extra supports for writing assignments and provided specialized speech and language therapy targeting language pragmatic and formulation skills and special education services targeting executive functions and writing. In addition, he got help from a peer buddy on the playground to ensure inclusion in games and activities. John's school services were supplemented by outpatient services in social skills training and anxiety reduction techniques by a skilled therapist. His parents also received coaching in how to organize John's day and to set up a comprehensive reward system.

School-Based Recommendations School-based services in private schools are up to the discretion of the school. Some private schools offer specialized services to students, but they are not required to do so and may charge an additional fee. There are three options for services in public schools: 1) informal supports and accommodations negotiated with the child's teacher or the student support team, 2) a 504 plan to provide formalized accommodations that will allow a student with a disability to access the general curriculum, or 3) an IEP to formulate specific and measurable goals. In order to make progress toward meeting those goals, formalized services must usually be provided to the student (e.g.,

special education or speech-language therapy), and those services may be provided in a mainstream classroom, resource room, special classroom, or special school depending on the student's needs. Every student has a right to an appropriate education in the least restrictive environment possible (see Chapter 33). School-based services are generally well coordinated across disciplines. The quality of school-based services varies widely, however, from county to county and sometimes even from one school to another within a county. Having an outside professional review the services a child is receiving and monitor the progress the child is making is helpful for many families. If the family needs extra help navigating the school-based meetings, they may want to hire an educational specialist/advocate, a professional who knows the laws and the local schools, or a special education attorney if the family is heading toward mediation or a due process hearing. The free-access web site <http://www.wrightslaw.com> has more information on advocating for special education services.

Home/Outpatient-Based Services Getting services through a disconnected service system, as most out-of-school systems are, requires active advocacy skills from parents. Parents often find themselves filling multiple roles, including case manager and treatment coordinator, as well as having to obtain insurance authorizations, schedule and transport their child, and act as a treatment provider at home. Many parents need help in the identification and coordination of treatment team members. All treatment providers and key school personnel should see the assessment report. Communication among team members is vital. If the child's needs are complicated, a short conference call is useful to make sure that everyone has the same information and that there is consistency across settings. Over time, it is useful to review recommendations and discuss suggestions that have not yet been tried or next steps to consider. Risk factors identified in the report should also be monitored. Too often, an evaluation is reviewed once and then ignored when in fact it contains data relevant to the treatment plan for a schoolchild for several years after the assessment. The final step of effective implementation of an assessment is following up at the appropriate time for recommended reevaluations.

SUMMARY

- The primary purpose of neuropsychological assessment is to educate the child, his or her family, and the treatment and educational team about the child's profile of cognitive strengths and weaknesses and emotional and behavioral functioning.

- This profile is used to identify where the child is at risk of difficulty and to develop a plan for making environmental accommodations or for teaching the child missing skills so that those risks can be mitigated.
- A successful model of neuropsychological assessment requires the integration of understanding brain structure and function, development, and context. Understanding the neural substrate available to a child at his or her stage of development, as well as the demands placed by the contexts the child inhabits, informs the description of the child's neuropsychological profile and treatment plan.
- The neuropsychological profile typically addresses multiple domains of functioning, including general intelligence, attention, executive, language, visual, learning and memory, social cognition, sensory, motor, emotional, adaptive, and academic performance.
- Appropriate referral questions, followed by thorough assessment and effective dissemination of findings and recommendations to families and treatment teams, maximizes the impact of neuropsychological assessment on children's lives.

Appendix 13.1 Examples of Widely Used Neurodevelopmental Measures Organized by Functional Domain

Measure	Scale name	Age range	Admin. time	Advantages	Disadvantages	References
<i>General intelligence</i>						
Bayley Scales of Infant Development, Third Edition (Bayley-III)	Adaptive behavior, cognitive, language composite, motor composite	1–42 months	50–90 min.	One of the only instruments available in the age range, recently restandardized, extended floors and ceilings, improved evidence of reliability and validity	Difficult to administer and confounded by significant language demands	Bayley (2006)
Mullen Scales of Early Learning (AGS Edition)	Early learning composite Gross motor; visual reception; fine motor; receptive language; expressive language	Birth–68 months	~15 min. (for 1 year olds) to 60 min. (for 5 year olds)	Limited language demands	Old normative data	Mullen (1995)
Wechsler Intelligence Scales for Children—Fifth Edition (WISC-V)	Full scale, verbal comprehension, visual spatial, working memory, fluid reasoning, processing speed	6–16 years	60–90 min.	Most widely used test of cognitive ability in children and adolescents; excellent norms; familiar; stronger measurement of working memory than previous	Not tied to strong theory of intelligence; relatively weak assessment of processing speed	Wechsler (2014)
Wechsler Adult Intelligence Scales (WAIS-IV)	Full scale, verbal comprehension, perceptual reasoning, working memory, processing speed, general ability	16–90 years	60–90 min.	Reliable, good norms, commonly administered	Not tied to strong theory of intelligence; relatively weak assessment of processing speed and working memory	Wechsler (2008)
Wechsler Abbreviated Scale of Intelligence (WASI-II)	Full scale, verbal comprehension, perceptual reasoning	6–90 years	30 min.	Validated as a brief measure of verbal, nonverbal, and general cognitive ability; very precise scores; Matrix Reasoning can be administered nonverbally	No coverage of processing speed, working memory, or other aspects of cognitive ability	Wechsler (2011)
Comprehensive Test of Nonverbal Intelligence (CTONI-2)	Pictorial analogies, geometric analogies, pictorial categories, geometric categories, pictorial sequences, geometric sequences	6 years–89 years, 11 months	60 min.	Minimizes cultural bias, good for children with language disorders	Less predictive of some aspects of functioning than verbally loaded scales	Hammill, Pearson, and Wiederholt (2009)
Leiter International Performance Scale, Third Edition	Cognitive; attention & memory	3–75 years	20–45 min.	Covers wide age range; minimal bias across cultures; strong theoretical model guiding revision	Special training may be needed for good standardization, though the reduction from 20 subtests to 10 subtests in the third edition helps.	Roid, Miller, Pomplun, and Koch (2013)
Differential Abilities Scale-II (DAS-II)	General Cognitive Ability, Verbal Ability, Nonverbal Ability, Spatial Ability	2.5 years–17 years, 11 months	60 min.	Good norms, conceptual model, strong psychometrics, nonverbal subtests can be administered without language	No working memory or processing speed	Elliott (2007)

Attention						
Conners' Continuous Performance Test (3rd ed.)	Total score (also a short form, a <i>DSM</i> form, and a global form)	6–18 years	5–20 min.	Parent, teacher, and youth forms; includes <i>DSM-IV</i> content; extensive research base; includes validity scales	Cumbersome to score without computer software; short forms validated in embedded version (not separate administration)	Conners (2008)
Continuous Performance Test–II (CPT)	Sustained attention, omissions, commissions, variability, standard error	3+ years	15–20 min.	Standardized task that measures multiple performance facets of attention	Relatively small number of minorities included in the norm sample; overall mild correlations between CPT and ADHD rating scales	Conners and MHS Staff (2004)
Executive functioning						
Behavior Rating Inventory of Executive Functioning (BRIEF-2)	Global executive composite	5–18 years	10–15 min.	Parent and teacher forms; inexpensive; collateral source of information about executive functioning Comprehensive coverage of subdomains of executive functioning; ecologically valid measure; used extensively in research with good sensitivity; easy to administer and complete	Informant ratings are susceptible to bias; report of everyday executive function does not necessarily accurately parse subdomains of executive function.	Gioia, Isquith, Guy, and Kenworthy (2000)
Rey Complex Figure Test	Copy strategy	6–89 years	45 min., including 30-min. delayed interval	New manual (1996) improves scoring criteria and guidelines, as well as norms Developmental scoring norms capture problem-solving strategy (as opposed to outcome score), which is a key correlate of executive functions that is often not addressed	Wide developmental variation and limited normative sample compromise sensitivity Scoring system is complex and prone to error; requires specific training for adequate accuracy	Meyers and Meyers (1996)
Wisconsin Card Sorting Test (WCST)	Perseverative errors	6.5 years–89 years, 11 months	20–30 min.	Relevant construct for neurotoxicity	Difficult to reliably score if not using computer administration; not representative norms; complex relationship between scales and executive function	Heaton, Chelune, Talley, Kay, and Curtiss (1993)
Language						
Goldman-Fristoe Test of Articulation-3	Sounds in words, sounds in sentences, stimulability	2–21 years	15 min.	Strong standardization sample; good norm-referenced scores	Technical information based on administrations by speech pathologists; unclear how results would vary with less trained raters; use with caution with speakers of nonstandard English	Goldman and Fristoe (2015)

(continued)

Appendix 13.1 (continued)

Measure	Scale name	Age range	Admin. time	Advantages	Disadvantages	References
Preschool Language Scale, Fifth Edition (PLS)	Auditory comprehension, expressive communication	Birth–7 years, 11 months	45–60 min.	Spanish version available, with dual-language administration and scoring Spanish norms developed with both monolingual and bilingual children	Potential for variability in administration and scoring means that a high degree of training is needed for consistency	Zimmerman, Steiner, and Pond (2011)
Clinical Evaluation of Language Fundamentals (Fifth Edition) (CELF-5)	Core language, receptive language, expressive language, language content, language memory, pragmatics	5–21 years (preschool version also available)	30–45 min.	Easy to learn; computer-assisted scoring; focuses on specific skills and areas of functioning (versus achievement) Telepractice option available (Q-Global)		Wiig, Semel, and Secord (2013)
California Verbal Learning Test, Children's Version (CVLT-C)	Verbal learning, memory	5–16 years	15–20 min.	Widely used test of verbal learning and memory, short, measures recognition and recall		Delis, Kramer, Kaplan, and Ober (1994)
Test of Problem Solving Child and Adolescent (TOPS 3 Elementary)	Pragmatic language	6 years–12 years, 11 months	35 min.	Assesses language-based critical-thinking skills	Lengthy to administer	Bowers, Huisingh, and LoGiudice (2005)
<i>Visual perceptual</i>						
Beery-Buktenica Developmental Test of Visual Motor Integration (6th Edition)	Visual motor integration, visual perception, motor coordination	2–99 years for full form	10–15 min.	Culture-free, easy to administer, used in many countries, can be administered in groups	Scoring somewhat difficult	Beery and Beery (2004)
Performance subtests from IQ measures (e.g., WISC, DAS)	Block design, digit cancellation, copy, etc.	Various	Various	Well-normed; clear scoring; readily available	Not validated as stand-alone tests; scores on single scale driven by multiple factors	Elliott (2007); Wechsler (2014)
<i>Learning/memory</i>						
Wide Range Assessment of Memory and Learning (WRAML-2)	Visual memory index, verbal memory index, attention/concentration, general memory index, screening memory index	5 years –84 years, 11 months	60 min. for all core subtests	Wide age range; new norms; stronger factor structure than earlier version	Lengthy administration time; often only specific subtests are used	Sheslow and Adams (2003)

<i>Social cognition</i>						
Social Responsiveness Scale, Second Edition (SRS-2) Parent and teacher forms	Total, social cognition, social communication, social awareness, social motivation, restricted interests, and repetitive behavior	2.5–18 years	15–20 min.	Exceptional evidence of construct validity; inexpensive to administer; gender normed	No age norms	Constantino and Gruber (2012)
Autism Diagnostic Schedule, Second Edition (ADOS-2)	Social affect, restricted and repetitive behavior, overall total, comparison score	12 months–adult	40–60 min.	Modules chosen based on language skill, good validity, play- and interview-based assessment	Difficult to administer and score reliably, extensive training needed	Lord, Rutter, DiLavore, and Risi (2012)
Autism Diagnostic Interview, Revised (ADI-R)	Communication, social, repetitive interests/behaviors	4 years–adult	1.5–2.5 hours	Comfortable for parents, thorough	Retrospective parent report, difficult to administer and score reliably, extensive training needed, lengthy	Rutter, Le Couteur, and Lord (2003)
<i>Motor/sensory</i>						
Peabody Developmental Motor Scales	Fine motor quotient, gross motor quotient, plus 9 subtest scores	Birth–72 months	2–3 hours (20–30 min. per subtest)	Minimal training needed because of clear instructions and objective scoring; easy to administer	Limited data on children with special needs; kit does not include all materials needed for administration; small objects are a choke hazard and need cleaning if mouthed	Folio and Fewell (2000)
Digital Finger Tapping	Digital finger tapping	Various norms; college student for digital version	10 min. with scoring	Easy to administer; electronic counter enhances accuracy	Poor norms; limited psychometric data; primarily suited to research use with comparison groups	Brandon and Bennett (1989)
Finger Tapping (Halstead-Reitan)	Finger tapping	15–64 years	10 min. with scoring	Easy to administer; widely recognized test	Small and dated norms	Reitan (1979)
Finger Tapping (Findels and Weight Meta-Norms)	Finger tapping	5–14 years	10 min. with scoring	Easy to administer	Pools data from 20 different studies to create “norms”	Baron (2004)
<i>Emotional adjustment</i>						
Achenbach Child Behavior Checklist	Total problems, externalizing, internalizing, attention problems	1.5 years–young adult	10–15 min.	Multiple versions, multiple informants, forms and norms for multiple age ranges, large research and clinical literature with wide variety of medical conditions	Omits some content likely to be relevant, including theory of mind, mania scale; Scales do not map directly onto psychiatric diagnoses	Achenbach and Rescorla (2001)
Aberrant Behavior Checklist (ABC)	Irritability, lethargy, stereotypy, hyperactivity, inappropriate speech	5–51+ years	~5 min. for a rater familiar with subject’s behavior	Good content coverage; sensitive to treatment effects	Manual provides incomplete psychometric information; although often used as parent or teacher rating, less validation of these formats	Aman and Singh (1986)

(continued)

Appendix 13.1 (continued)

Measure	Scale name	Age range	Admin. time	Advantages	Disadvantages	References
Infant-Toddler Social and Emotional Assessment (ITSEA)	Problem total; competence total; also externalizing, internalizing, dysregulation, competence, and maladaptive item clusters	12–35 months	20–30 min.	Parent form, parent interview form, and childcare provider form; Spanish translation available; brief screening version (BITSEA)	Little technical information about childcare provider or Spanish forms	Briggs Gowan and Carter (2006)
<i>Adaptive/academic</i>						
Adaptive Behavior Assessment System, Third Edition (ABAS-3)	Parent form, general adaptive, composite	Birth–89 years	15–20 min.	Multiple versions for different ages and parents and daycare providers; extensive construct validity	Like any parent checklist, ABAS is susceptible to misinterpretation and bias	Harrison and Oakland (2015)
Vineland Adaptive Behavior Scale, Third Edition (Vineland-3)	Adaptive behavior composite, communication, daily living skills, socialization, motor skills (optional), maladaptive behavior (optional)	Birth–90 years	20–60 min. 15–20 min.	Well-validated in multiple clinical groups Interview and informant-report versions; multiple versions for different ages and parents and daycare providers; extensive construct validity	Time and expertise intensive measure for the interview version; can take more than 1 hour to complete Administration of interview version requires expertise gained through graduate-level training programs in psychology or social work	Sparrow, Cicchetti, and Saulnier (2005)
Wide Range Achievement Test 4 (WRAT-4)	Word reading, sentence comprehension, reading composite, spelling, math computation	5 years–94 years, 11 months	15–25 min. for ages 5 to 7 for whole test; 30–45 min. for over age 7 for whole test	Short, alternative forms allows retesting, part can be administered in group format	Captures basic learning difficulties with reading decoding, and math computation, but is not sensitive to learning disabilities associated with executive function, processing speed, motor output, reading comprehension, or written expression	Wilkinson and Robertson (2006)
Woodcock-Johnson–IV	Cognitive abilities, achievement, and oral language	2–90+ years	Variable, ~5 min. per test	Relatively easy to administer; sensitive to the effects of processing speed and motor output deficits on academics		Schrank, McGrew, and Mather (2014)

PART **IV**

Developmental Disabilities

CHAPTER 14

Intellectual Disability

Bruce K. Shapiro and Mark L. Batshaw

Upon completion of this chapter, the reader will

- Understand the definition of the term *developmental delay* and the implications of the terms *mental retardation* and *intellectual disability*
- Be aware of the various causes of intellectual disability
- Recognize the various interventions in intellectual disability
- Be aware of the different levels of functioning and independence that individuals with intellectual disability can achieve

Intellectual disability refers to a heterogeneous group of disorders that have significant deficits in reasoning that impairs the individual's ability to function in day to day life. People with intellectual disability have the capacity to learn, but they have difficulty adapting that knowledge to novel situations. There are many different causes of intellectual disability. Consequently, the range of the cognitive impairment seen in intellectual disability is wide and comorbid disorders are the rule. A multimodal, individualized approach to management can optimize the individual's ability to participate in everyday life.

■ ■ ■ CASE STUDY

Daniel's mother, Marina, noticed many signs in his early development that indicated atypical development. (In the following paragraphs, the typical ages for these developmental milestones are indicated in parentheses after the age at which Daniel achieved them).

As an infant, Daniel showed little interest in his environment and was not very alert. Although Marina tried to

breastfeed him, his suck was weak, and he frequently regurgitated his formula. He was floppy and had poor head control. His cry was high pitched, and he was difficult to comfort. He would sit in an infant seat for hours without complaint.

In social and motor development, Daniel was delayed. With regard to his social development, Daniel smiled at 5 months (2 months) but was not very responsive to his parents' attention. He did not start babbling until 13 months (6 months). With regard to gross motor development, Daniel could hold his head up at 4 months (1 month), roll over at 8 months (5 months), and sit up at 14 months (6 months). He transferred objects from one hand to the other at 14 months (5 months).

When evaluated with the Bayley Scales of Infant Development—Third Edition (BSID-III; Bayley, 2006) at 16 months of age, Daniel's mental age was found to be 7 months and he received a mental developmental index (similar to an intelligence quotient [IQ] score) of less than 50. He progressed from an early intervention program to a special preschool program. Prior to school entry at age 6, Daniel was retested on the Stanford-Binet

Intelligence Scales, Fifth Edition (SB5; Roid, 2003). His score indicated a mental age of 2 years and 8 months and an IQ score of 40. Concomitant impairments in adaptive behavior were demonstrated by the Vineland Adaptive Behavior Scales, Third Edition (Vineland-3; Sparrow, Chrichtetti, & Saulnier, 2016), which revealed communicative, self-care, and social skill challenges.

Thought Question:

How early can you determine that a child has intellectual disability, and why does it matter?

DEFINING INTELLECTUAL DISABILITY

The term *intellectual disability* (ID) has replaced the older term *mental retardation*. This change was codified in federal legislation in 2010, when Rosa's Law (Pub. L. 111-256) was enacted, which changed the term used in federal legislation from *mental retardation* to *intellectual disability*. The federal definition of the term itself did not change and comes from the Individuals with Disabilities Education Improvement Act (IDEA) of 2004 (PL 108-446), which defines intellectual disability as "significantly sub-average general intellectual functioning, existing concurrently with deficits in adaptive behavior and manifested during the developmental period that adversely affects a child's educational performance." Two other authoritative groups, the American Psychiatric Association (APA, 2013) and the American Association on Intellectual and Developmental Disabilities (AAIDD; Schalock et al., 2009) maintain the same three criteria of adaptive behavior deficits, subaverage intellectual function, and onset during the developmental period. Yet, their definitions shift the focus from IQ to adaptive behavior deficits. It is likely that the term *intellectual disability* will be replaced by the term *intellectual developmental disorder*. The latter has been proposed by the World Health Organization's *International Classification of Diseases* (ICD-11) nomenclature as a health condition and is defined as "a group of developmental conditions characterized by a significant impairment of cognitive functions which are associated with limitations of learning, adaptive behavior and skills" (Bertelli, Munir, Harris, & Salvador-Carulla, 2016).

Adaptive Impairments

Individuals fulfilling the diagnosis of intellectual disability must demonstrate adaptive deficits that impair their ability to adapt to or function in daily life when compared with peers of similar age or culture. Indeed, it is the deficits in adaptive function that bring children

to our attention. These impairments limit or restrict an individual's participation and performance in one or more aspects of daily life activities, such as communication, social participation, function at school or work, or personal independence at home or in community settings. The limitations result in the need for ongoing support at home, school, work, or independent life. Typically, adaptive behavior is measured using individualized, standardized, culturally appropriate, and psychometrically sound tests (APA, 2013).

The AAIDD (Schalock et al., 2009) divides adaptive function into three domains: conceptual, practical, and socialization. Conceptual skills include such things as language and literacy, money, time, number concepts, and self-direction. Practical skills include the activities of daily living, occupational skills, health care, travel/transportation, schedules/routines, safety, use of money, and use of the telephone. Social skills encompass interpersonal skills, social responsibility, self-esteem, gullibility, naïveté, social problem-solving, and the ability to follow rules/obey laws and to avoid being victimized. The AAIDD definition of intellectual disability requires deficits to exist in one of the three domains of adaptive behavior.

Intellectual Functioning

There is general agreement that the definition of intellectual disability requires that a person must have significantly subaverage intellectual functioning and impairments in adaptive abilities with onset during the developmental period; however, disagreements over operationalizing this definition have arisen for both biological and philosophical reasons. The first controversial issue is that the definition involves the assessment of intellectual functioning. The average level of intellectual functioning in a population corresponds to the apex of a bell-shaped curve (Figure 14.1). Two standard deviations on either side of the mean encompass 95% of a population sample and approximately defines the range of typical intellectual functioning. By definition, the average IQ score is 100, and the standard deviation (a statistical measure of dispersion from the mean) of most IQ tests is 15 points. Historically, a person scoring more than 2 standard deviations below the mean, or below an IQ of 70, has been considered to have intellectual disability.

Statisticians, however, point out that there is a measurement variance of approximately 5 points in assessing IQ by most psychometric tests. In other words, repeated testing of the same individual will produce scores that vary by as much as 5 points (American Psychiatric Association, 2000). Using this schema, intellectual disability would be diagnosed in an individual with

Figure 14.1. Bimodal distribution of intelligence. The mean IQ score is 100. An IQ score of less than 70, or 2 standard deviations below the mean, can indicate intellectual disability. The second, smaller curve takes into account individuals who have intellectual disability because of birth trauma, infection, inborn errors, or other organic causes. This explains why more individuals have severe to profound intellectual disability than are predicted by the familial curve alone. (From Zigler, E. [1967]. Familial mental retardation: A continuing dilemma. *Science*, 155, 292–298. <http://www.aaas.org>. Reprinted with permission from AAAS.)

an IQ score between 70 and 75 who exhibits significant impairments in adaptive behavior, whereas it would not be diagnosed in an individual with an IQ of 65 to 70 who demonstrates adaptive skills in the typical range.

Measured IQ may not be stable over time. Children may grow into or out of intellectual disability. Some young children may evidence a decelerating trajectory of intellectual growth and move into the diagnosis as adolescents. Alternatively, children may have an intellectual growth rate that accelerates over time and grow out of the diagnosis. Others develop sufficient adaptive behavior to no longer meet the criteria for intellectual disability.

In addition to changes in the individual, there appears to be a change in performance on IQ measures in a population. This phenomenon, known as the Flynn effect, holds that there is a relationship between the length of time that an instrument is in use and the individual's score on that instrument. This is based on the observation that the mean IQ increased on every restandardization sample in a population for major intelligence tests (Schalock et al., 2009).

Cognitive functioning is not always uniform across all neurodevelopmental domains. An example

is found in a study by Wang and Bellugi (1993), who compared neuropsychological testing results in children with Down syndrome and Williams syndrome. Although the full-scale IQ scores in both groups were similar, the pattern of cognitive strengths and weaknesses was very different. The individuals with Williams syndrome had much stronger skills in language but much poorer visual-perceptual abilities than did the children with Down syndrome. When volumetric analysis of magnetic resonance imaging (MRI) scans was performed, the cortical areas involved in language acquisition were much more developed in individuals with Williams syndrome; conversely, the basal ganglia area that is involved in visual-perception was more developed in individuals with Down syndrome.

Beyond any measurement variability, a more fundamental concern of some theorists is the underlying value of an IQ score. Gardner (1983) challenged the dichotomous (verbal-vs.-performance) structure of intelligence assessed by many IQ tests. He proposed that intelligence comprises a wider range of abilities, not only the traditional linguistic and logical-mathematical skills, but also musical, spatial, bodily-kinesthetic, and interpersonal characteristics. However, this approach has not gained wide acceptance as it does not have a clear neuropsychological or neuroanatomical basis. Although it is acknowledged that a single IQ score averages a person's cognitive abilities and may not capture all forms of intelligence, there is evidence that a significantly subnormal IQ score is a meaningful predictor of future cognitive function.

Finally, there are the concerns over predictive validity and cultural bias. Infant psychological tests are notoriously poor predictors of adult IQ scores, although they clearly differentiate severe impairments from typical functioning. In addition, cultural bias has been suggested as one explanation for differences in IQ scores found among individuals from various racial, ethnic, and socioeconomic groups.

CLASSIFICATION OF INTELLECTUAL DISABILITY

Intellectual disability is comprised of a group of conditions that arise from many different causes and that have many different expressions. Although the diagnosis of intellectual disability is important, the classification of intellectual disability is equally important. Etiologic evaluation, neurobiological mechanisms, management, planning, and prognosis are all predicated on the ability to classify the disorder. There are many methods for classification, but this chapter

focuses on five: 1) degree of intellectual impairment, 2) adaptive behavior, 3) required supports, 4) domains of disability, and 5) etiology.

Degree of Intellectual Impairment

There is controversy about classifying the levels of intellectual disability. In the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* published by the APA (*DSM-IV*), an individual was classified as having mild intellectual disability if his or her IQ level was 50 to approximately 70, moderate intellectual disability if his or her IQ level was 35 to approximately 50, severe intellectual disability if his or her IQ level was 20 to approximately 35, and profound intellectual disability if his or her IQ level was below 20 to 25 (APA, 2000). While this classification has been met with widespread acceptance in the medical community, it should be noted that classification solely on the basis of IQ is incomplete and does not capture all of an individual's adaptive abilities. *DSM-5* abandoned specific IQ scores as a diagnostic criterion, although it retained the general notion of functioning two or more standard deviations below the general population.

It has also been suggested that intellectual disability should be simply dichotomized into mild (an IQ score of 50 to approximately 70) and severe (an IQ score below 50). This suggestion is based on the discrete biological division between mild intellectual disability and the more severe forms, with different etiologies and outcomes. This dichotomy has not been widely accepted for clinical purposes because the medical, educational, and habilitative needs are quite different between individuals with moderate impairments and those with profound impairments.

Adaptive Behavior

In the *DSM-5*, the APA has advocated for classifying intellectual disability by adaptive behavior (APA, 2013). This classification is addressed below in the section on outcomes. While this classification may be a more complete view of a person's everyday function in conceptual, social, and practical domains than classification by degree of intellectual impairment, it is most useful when dealing with adults. This system is less useful in developing children and when encountering discordance in the domains of adaptive behavior.

Required Supports

The AAIDD takes a different approach in defining the degree of severity of intellectual disability, relying not

on IQ scores, but rather on the patterns and intensity of needed support (i.e., intermittent, limited, extensive, or pervasive support). This definition marks a philosophical shift from an emphasis on degree of impairment to a focus on the abilities of individuals to function in an inclusive environment. This shift is controversial because it assumes that adaptive behaviors can be independent of cognition, and it does not provide clear guidelines for establishing diagnostic eligibility of children with IQ scores in the upper limits of the range connoting intellectual disability. This chapter (and other chapters throughout this book) uses the *DSM-IV* categories in discussing medical issues and the AAIDD's categories in discussing educational and other interventions, emphasizing the capabilities rather than the impairments of individuals with intellectual disability.

Domains of Disability

Another way to classify intellectual disability is to use the terminology developed by the National Center for Medical Rehabilitation Research (Msall, 2005). This model defines five domains: pathophysiology, impairment, functional limitation, disability, and societal limitation (Table 14.1). Pathophysiology focuses on the cellular, structural, or functional events resulting from injury, disease, or genetic abnormality that underlie the developmental disability. Impairment refers to the losses that result from the pathophysiological event. Functional limitation describes the restriction or lack of ability to perform a normal function. Disability is the inability to perform activities or limitation in the performance of activities. Societal limitations focus on barriers to full participation in society. Table 14.1 illustrates how this system can be applied to children with Prader-Willi syndrome, fetal alcohol spectrum disorder, and Down syndrome. The advantage of this approach is that it leads directly from diagnosis to treatment and that it focuses on how to overcome limitations. The approach also acknowledges the change in emphasis in the diagnosis of intellectual disability from impairment and functional limitations to disability and societal limitations. This is consistent with the move from focusing on the intensity of the disability (e.g., severe) to the support needed to function in society (e.g., requiring extensive support). This approach is also in keeping with the process for developing an individualized education program (IEP) for a school-age child (see Chapter 33).

Etiology

Classification of intellectual disability by cause (etiology) has increased as the ability to identify genetic

Table 14.1. Relationship between disability domains and treatments in Prader-Willi syndrome, fetal alcohol spectrum disorder, and Down syndrome

Pathophysiology	Impairment/ Disorder	Functional limitation	Disability	Societal limitation	Treatment
Deletion in chromosome 15	Prader-Willi syndrome	Intellectual disability Feeding disorder	Learning and adaptive skills below age level Obesity	Noninclusive school settings Stereotyping because of obesity and intellectual disability Underestimating abilities	Education Activities to promote weight loss
<i>In utero</i> alcohol exposure	Fetal alcohol spectrum disorder	Intellectual disability Behavioral disturbances	Learning and adaptive skills below age level but variable Severe hyperactivity common	Noninclusive school settings Stigma because of etiology Overestimating abilities because of variable cognitive profile	Education Mental health Interventions as required
Trisomy 21	Down syndrome	Intellectual disability	Learning and adaptive skills below age level	Noninclusive school settings Stereotyping because of intellectual disability Underestimating abilities	Education programs to raise societal awareness

Source: Msall et al. (2003).

Note: Even though each child may have similar degrees of intellectual disability, the pattern of disability and type of treatments may vary widely.

causes of intellectual disability has advanced. It has also led to the establishment of family support and advocacy groups for specific disorders (e.g., Down syndrome, fragile X syndrome, and Williams syndrome). In one study, the etiology of intellectual disability was able to be divided into five classification groups at 4 years of age: environmental (44.4%), genetic (20.5%), idiopathic (12.6%), neonatal sequelae (13.2%), and other diseases (9.3%) (Karam et al., 2016). Grouping by etiology provides greater biologic homogeneity and facilitates neurobiologic research that elucidates the brain mechanisms of intellectual disability and the potential for prevention, amelioration, or cure. The decreasing cost and increased availability of genetic testing have enhanced our ability to diagnose etiologies of many individuals with moderate-profound intellectual disability, and it is now part of the diagnostic regimen for these individuals (see Chapter 12).

PREVALENCE OF INTELLECTUAL DISABILITY

The epidemiology of intellectual disability suggests that there are two distinct populations: Mild intellectual disability is more likely to be associated with social disadvantage and familial factors (Reichenberg et al., 2016), whereas severe intellectual disability is more typically linked to a biological/genetic origin (Karam et al., 2015). There is often, however, an interaction between nature and nurture. Postnatal environmental influences

mediate biological processes through mechanisms that may be indirect (e.g., epigenetics; see Chapter 1) and are not fully understood at the present. In addition, postnatal environmental factors may affect the expression of neurodevelopmental dysfunction. For example, a child may have an initial biological insult (e.g., intrauterine growth restriction [IUGR]) that can be compounded by postnatal environmental variables, such as poor nutrition, social disadvantage, or physical abuse). Mothers who never finished high school are four times more likely to have children with mild intellectual disability than are women who completed high school (Mendola, Selevan, Gutter, & Rice, 2002). The explanation for this is unclear, but it may involve a genetic component (i.e., inheritance of a cognitive impairment) and socioeconomic factors (e.g., poverty and poor nutrition). The application of early intervention services to high-risk infants who are also at socioeconomic risk has resulted in improved cognitive outcomes (see Chapter 31).

The prevalence of intellectual disability depends on the definition used, the method of ascertainment, and the population studied. In various studies it has ranged between 6.7 (Boyle et al., 2011) and 10.37 (Van Naarden Braun et al., 2015) per 1,000. Males are more likely to manifest intellectual disability than females with a ratio of approximately two to one.

The variability in the prevalence of intellectual disability seems to be related to mild intellectual disability. The prevalence of severe intellectual disability is relatively constant across countries and across time, accounting for 0.3%–0.5% of the population. By

contrast, the prevalence of mild intellectual disability shows significant variability.

According to statistics of IQ tests, 2.5% of the population could be predicted to have intellectual disability, and another 2.5% could be predicted to have superior intelligence (Figure 14.1). The IQ scores of 85% of individuals with intellectual disability (about 2.1% of the population) should fall in the range of mild intellectual disability (2 to 3 standard deviations below the mean). If, however, individuals who score low on IQ tests because of social disadvantage are excluded from the count, the prevalence of mild intellectual disability is only about half these predictions, somewhere between 0.8% and 1.2% (Heikura et al., 2003). Other factors that impact the prevalence of mild intellectual disability are 1) diagnostic overshadowing (e.g., providing a primary diagnosis of learning disability, language disorder, autism, developmental delay, or a mental health disorder rather than intellectual disability), 2) improved evaluation instruments, 3) professional disinclination to use this diagnosis in children, and 4) the inappropriate use of the term *developmental delay* in older children. Diagnostic substitution of autism spectrum disorder (ASD) as a primary diagnosis instead of intellectual disability has had an especially important impact on the prevalence of intellectual disability (see Chapter 18). Finally, it is possible that the prevalence of mild intellectual disability is decreasing because of public welfare (improved nutrition), health (anticipatory guidance), and education (early intervention) measures that have been implemented.

Whatever the prevalence, the diagnosis of intellectual disability appears to peak at 10–14 years of age, acknowledging that, as expected, children with mild impairments are identified significantly later than those with more severe impairments.

Etiology

The specific origins of mild intellectual disability are identifiable in less than half of affected individuals (Moeschler, Shevell, & American Academy of Pediatrics Committee on Genetics, 2006). The most common biological causes are certain genetic/chromosomal syndromes—for example, velocardiofacial syndrome; fetal deprivation (e.g., IUGR); perinatal complications (e.g., encephalopathy or infection); and intrauterine exposure to drugs of abuse, especially alcohol (Hoyme et al., 2016). Although definite genetic causes are less common (5% in mild intellectual disability versus 47% in severe intellectual disability), familial clustering of mild intellectual disability is common. In children with severe intellectual disability, a biological origin can be identified in about three quarters of cases. The most common identifiable causes are Down syndrome,

fragile X syndrome, and fetal alcohol spectrum disorders, which together account for almost one third of all currently detectable cases of severe intellectual disability (Hoyme et al., 2016).

One way of dividing the biological origins of intellectual disability is by their timing in the developmental sequence; in general, the earlier the problem, the more severe its consequences. This is consistent with finding a prenatal cause in about three quarters of individuals with an identifiable cause of severe intellectual disability (Gropman & Batshaw, 2010).

Chromosomal disorders (e.g., Down syndrome and Prader-Willi syndrome), certain single-gene defects (e.g., Rubinstein-Taybi syndrome, Hurler syndrome, and Kabuki syndrome), abnormalities of brain development that affect early embryogenesis (e.g., holoprosencephaly), and inborn errors of metabolism (see Chapter 16) are the most common and severe examples of biologic origin of intellectual disability. Together, these groups of genetically based causes of severe intellectual disability account for more than two thirds of identifiable causes and encompass more than 700 disorders (see <http://www.ncbi.nlm.nih.gov/omim> for more information).

Insults in the first and second trimesters as a result of substance abuse (e.g., fetal alcohol spectrum disorders), infections (e.g., cytomegalovirus), and other pregnancy problems (e.g., IUGR) occur in 10% of cases. Fetal deprivation in the third trimester due to placental damage, preeclampsia, or hemorrhage (see Chapter 6) and problems in the perinatal period (see Chapter 5) now account for less than 10% of identifiable causes of severe intellectual disability. Five percent are the result of postnatal brain damage, most commonly meningitis/encephalitis and traumatic brain injury (see Chapter 23). Overall, the recurrence risk in families with one child who has severe intellectual disability of unknown origin is 3%–9% (De Souza, Halliday, Chan, Bower, & Morris, 2009). Recurrence risk for intellectual disability of known origin, however, varies according to the cause. A family whose child has intellectual disability following neonatal meningitis does not have a significantly increased risk of having future affected children, whereas a woman who has had one child with a fetal alcohol spectrum disorder has a 30%–50% risk of having other affected children if she continues to abuse alcohol during pregnancy. The risk of recurrent Down syndrome ranges from less than 1% for trisomy 21 to more than 10% for a balanced translocation (De Souza et al., 2009). If the cause of intellectual disability is a Mendelian disorder (see Chapter 1), such as neurofibromatosis (an autosomal dominant trait), Hurler syndrome (an autosomal recessive trait), or fragile X syndrome (an X-linked trait), the recurrence risk ranges from 0%–50% depending on the inheritance pattern of the specific disorder.

DIAGNOSIS AND CLINICAL MANIFESTATIONS

Parents usually seek an evaluation for developmental delay when their child fails to meet specific developmental milestones (Table 14.2). In early infancy, these include a lack of responsiveness, unusual muscle tone or posture, and feeding difficulties. Between 6 and 15 months of age, motor delay is the most common concern. Language and behavior problems are the most common concerns after 18 months. If there is evidence of a significant developmental lag over time, the child should be sent for a comprehensive evaluation. Ideally, this evaluation should include an examination by a physician (pediatrician, neurodevelopmental pediatrician, developmental-behavioral pediatrician, child psychiatrist, geneticist, or pediatric neurologist) experienced in early childhood development and developmental disabilities, preferably in tandem with a clinical/educational psychologist and a social worker. Depending on the child's age and impairments, he or she also may need to be seen for early intervention assessment by an early childhood educator, advanced practice nurse, speech-language pathologist, or audiologist. If the child displays motor impairments, a physical therapist, an occupational therapist, and possibly a physiatrist should also be involved. Following the assessment, an individual family service plan (IFSP) is developed in the context of an early intervention program (see Chapter 31).

The term *global developmental delay* is most commonly used as a temporary diagnosis in young children who are at risk for developmental disabilities (Moeschler, Shevell, & American Academy of Pediatrics Committee on Genetics, 2014). Global developmental delay is applied to children younger than 5 years

of age who show a significant delay in achieving age-appropriate neurodevelopmental milestones in two or more of the major areas of child development: cognition, language, motor, self-help, and social-emotional development. It is often, although not always, predictive of a future diagnosis of intellectual disability (Riou, Ghosh, Francoeur, & Shevell, 2009).

Global developmental delay is recognized by the failure of the child to meet age-appropriate expectations based on the typical sequence of development. In the first months of life, delayed development can be manifested by a lack of visual or auditory response, an inadequate suck, and/or floppy or spastic muscle tone. Later in the first year, lack of language and motor delays in sitting and walking may suggest developmental delay (see Box 14.1). When a child continues to show significant delays in all developmental areas, intellectual disability is the most likely diagnosis.

Global developmental delay should be distinguished from the less specific developmental delay. Unfortunately, some medical practitioners continue to use the term *global developmental delay* long after the more specific diagnosis of intellectual disability can be made. Developmental delay, as an educational term, is defined by each state and may be used as a category of disability for children younger than age 9 years (IDEA, 2004).

Although developmental delay is the most common presenting concern in children who turn out to have intellectual disability, sensory impairment, ASD, or cerebral palsy, it does not always indicate a developmental disability. Isolated mild delays in expressive language (particularly in boys) or in gross motor abilities often resolve over time. These mild early delays, however, often signal an increased risk of the child developing academic or behavioral difficulties by school age.

Table 14.2. Presentations of intellectual disability by age

Age	Area of concern
Newborn	Dysmorphisms (structural abnormalities) Major physiologic dysfunction (e.g., eating, breathing)
2–4 months	Failure to interact with the environment (e.g., parent suspects child is deaf or has a visual impairment)
6–18 months	Gross motor delay (e.g., sitting, crawling, walking)
18 months–3 years	Language
3–5 years	Language Behavior (including play) Fine motor (e.g., cutting, coloring)
5+ years	Academic achievement Behavior (e.g., attention, anxiety, mood, conduct)

BOX 14.1 EVIDENCE-BASED PRACTICE**How Early Is Early?**

The Eden Cohort is a prospective longitudinal study that seeks to identify prenatal and early postnatal nutritional, environmental, and social determinants associated with children's health and typical or atypical development. This study comprised 1,100 infants who were recruited during their pregnancy and were followed through 5–6 years of age. Developmental milestones were collected in a standard fashion at 4, 8, 12, and 24 months. Questionnaires were derived from Brunet-Lezine Psychomotor Development Scale, a scale that is widely used in France. The MacArthur-Bates Communicative Development Inventories, short French version, a listing of 100 common words that a young child uses, was given at 24 months to quantify expressive vocabulary. The Wechsler Preschool and Primary Inventory was administered at 5–6 years. Data were grouped as gross motor, fine motor, socialization, and language domains (at 4 months groupings were motor and socialization/communication). Using multivariate analysis, the authors found that 1) a substantial amount of the later IQ variance was predicted by the 24-month evaluation; 2) early language skills more strongly predicted later IQ than other cognitive domains; and 3) several cognitive domains, but particularly language skills from the age of 8 months, predicted disabled children (IQ < 70) at 5–6 years. This study supports the contention that language is the best predictor of cognitive development and that developmental monitoring, even at very young ages, can detect children at risk for later intellectual disability (Peyre, Charkaluk, Forhan, Heude, & Ramus, 2017).

MEDICAL DIAGNOSTIC TESTING

No single method exists for detecting all causes of intellectual disability (Moeschler et al., 2014). As a result, diagnostic testing should be based on the medical history and a physical examination. For example, a child with an unusual facial appearance, a history of other affected family members, or multiple congenital anomalies should be referred to a geneticist. With the increased ability to identify genetic disorders, even minor anomalies may be worth pursuing (see Chapter 1). A male with unusual physical features or a family history of intellectual disability or ASD should probably have molecular studies for fragile X syndrome. A child with a progressive neurological disorder will need extensive metabolic investigation (see Chapter 16), and a child with seizure-like episodes should have an electroencephalogram (see Chapter 22). Finally, an MRI scan may be warranted in children with abnormal head growth or asymmetrical neurological findings (e.g., one side of the body weaker than the other). These tests, however, should not be seen as screening tools to be used in all children with intellectual disability because their yield of useful results is low unless there is a specific reason for performing the study and their cost is high.

Although these are the most common reasons for performing diagnostic tests, it now seems clear that some children with subtle physical or neurological findings also may have determinable biological origins

of their intellectual disability. It has been shown that a significant percentage of unexplained intellectual disability can be accounted for by genomic copy number variants (see Chapter 1). Chromosome microarrays and next-generation sequencing have revolutionized gene discovery in intellectual disability (Mefford, Batshaw, & Hoffman, 2012). Chromosome microarray analysis, which is recommended as a first-line test in the genetic workup of children with intellectual disability, developmental delays, autism, and congenital anomalies, provides a molecular diagnosis in 15%–20% of cases. Exome sequencing and whole-genome sequencing have moved rapidly into the diagnostic laboratory to identify specific genetic mutations (Rump et al., 2016; Zahir et al., 2017). It is important to mention that whole-genome sequencing is not clinically available yet but will be in the near future and will detect mutations that whole exome has not been able to identify. In addition, MRI scans have been found to document a significant number of subtle markers of cerebral malformations in about 10% of children with intellectual disability (Bar-kovich & Raybaud, 2004).

The extent to which one should investigate the cause of a child's intellectual disability is based on a number of factors. First, what is the degree of intellectual disability? One is less likely to find a biological cause in a child with mild intellectual disability than in a child with a severe disability. Second, is there a specific diagnostic path to follow? If there is a medical history, a family history, or physical findings pointing to

a specific cause, a diagnosis is more likely to be made. Conversely, in the absence of these indicators, it is difficult to choose specific tests to perform. Third, are the parents planning to have additional children? If so, clinicians are more likely to intensively seek disorders for which prenatal diagnosis or a specific early treatment option is available (e.g., inborn errors of metabolism). Finally, and most importantly, what are the parents' wishes? Different families have different levels of investment in searching for the cause of the intellectual disability. Some focus exclusively on treatment, while others are so directed at obtaining a diagnosis that they have difficulty accepting intervention until a specific cause has been determined. Both extremes and every perspective in between must be respected, and supportive anticipatory guidance should be provided in the context of parent education for the "here and now" as well as for the future.

PSYCHOLOGICAL TESTING

The routine evaluation for intellectual disability should include an individual intelligence test (see Chapter 13). The most commonly used tests in children are the BSID-III (Bayley, 2006), the SB5 (Roid, 2003), and the Wechsler scales: the Wechsler Preschool and Primary Scale of Intelligence–Fourth Edition (WPPSI-IV; Wechsler, 2012) and the Wechsler Intelligence Scale for Children–Fifth Edition (WISC-V; Wechsler et al., 2015).

As noted in the APA definition of intellectual disability, in addition to testing intelligence, adaptive skills (including social functioning) also should be measured. The most commonly used test of adaptive behavior is the Vineland-3 (Sparrow et al., 2016). Other tests of adaptive behavior that are used commonly include the Scales of Independent Behavior–Revised (Bruininks, Woodcock, Weatherman, & Hill, 1996) and the Adaptive Behavior Assessment System–Third Edition (ABAS-3; Harrison & Oakland, 2015).

Interpretation of Test Results

In infants and young children with typical development, there is substantial variability in IQ scores on repeated cognitive testing and consequently poor predictive validity until around 10 years of age. Accuracy is enhanced if repeated testing confirms a stable rate of cognitive development. The predictive value of infant tests is further limited because such tests are primarily dependent on nonlanguage items, whereas language skills remain the best predictors of future IQ scores. These tests do permit the differentiation of infants with

severe intellectual disability from typically developing infants, but they are less helpful in distinguishing between a typically developing child and one with a mild intellectual disability. In general, however, there is less variability seen with cognitive growth in children with intellectual disability, and so predictive validity is enhanced compared with children with typical development.

Although children with intellectual disability usually score below average on all subscale scores, they may score in the typical range in one or more performance areas in the Wechsler scales. Overall, these scales are quite accurate in predicting adult IQ scores when administered to school-age children. The evaluator, however, must ensure that conditions that may contribute to falsely low IQ scores do not confound the test performance. These include motor impairments, communication disorders, sensory impairments, speaking a language other than English, extremely low birth weight, or insufficient schooling; such conditions may invalidate certain intelligence tests and require modification of others. The presence of such conditions always requires caution with regard to interpretation.

There is usually, but not always, a good correlation between scores on intelligence tests and adaptive scales (Bloom & Zelko, 1994). Adaptive abilities, however, are more responsive to intervention efforts than are the cognitive abilities measured by IQ. Adaptive abilities are also more variable, which may relate to the underlying condition. For example, individuals with Prader-Willi syndrome have stable adaptive skills through adulthood, while individuals with fragile X syndrome may have increasing impairments over time (Jacquemont et al., 2004; Klaiman et al., 2014).

COMORBID/ASSOCIATED CONDITIONS

Intellectual disability is often accompanied by other impairments called comorbid conditions or associated deficits. Although a mild intellectual disability is frequently an isolated disorder, moderate-profound intellectual disability is often paired with medical, motor, behavioral, and communication disorders that affect the child's developmental outcome. The prevalence of these associated impairments correlates with the severity of the disability (Barnhill, Cooper, & Fletcher, 2017; Crocker, Prokic, Morin, & Reyes, 2014; Oeseburg, Jansen, Dijkstra, Groothoff, & Reijneveld, 2010a; Oeseburg, Jansen, Groothoff, Dijkstra, & Reijneveld, 2010b; Oliver & Richards, 2015; Robertson, Hatton, Emerson, & Baines, 2015). Comorbid conditions include cerebral palsy, seizure disorders, communication disorders, sensory impairments (hearing and/or visual deficits),

and psychological/behavioral disorders (e.g., mood disorders, ASD, attention-deficit/hyperactivity disorder [ADHD], self-injury, aggression, and conduct disorders; Table 14.3).

Approximately 20% of children with severe intellectual disability have cerebral palsy, which may also be associated with feeding problems and failure to thrive. Seizure disorders also occur in about 20% of children with intellectual disability. Communication deficits (speech-language impairments) beyond those related to the cognitive impairment also are frequent. Finally, psychological and behavior disorders occur in up to half of children with intellectual disability (Cooper & van der Speck, 2009). In considering intervention strategies, identifying these comorbid conditions and working toward their treatment is essential in order to obtain an optimal outcome.

Associated deficits may make it difficult to distinguish intellectual disability from other developmental disabilities. Certain distinguishing features, however, frequently exist. In isolated intellectual disability, language and nonverbal reasoning skills are significantly delayed, whereas gross motor skills tend to be less affected. Conversely, in cerebral palsy, motor impairments are often more prominent than cognitive impairments. In communication disorders, expressive and/or receptive language skills are more delayed than nonverbal reasoning skills. In ASD, social skills impairments and atypical behaviors are superimposed on cognitive (especially communication) impairments. In some instances, repeated assessments may be necessary to determine the primary developmental disability.

TREATMENT, MANAGEMENT, AND INTERVENTIONS

The most useful treatment approach for children with intellectual disability consists of multimodal efforts

Table 14.3. Percentage of children with intellectual disability who have associated chronic health conditions

Epilepsy	22%
Cerebral palsy	19.8%
Hearing problems	4.5%
Vision problems	2.2%–26.8%
Down syndrome	11.0%
Fragile X	1.9%
Autism spectrum disorder	17.2%
ADHD/hyperkinetic disorder	9.5%
Conduct disorder	5.1%
Oppositional defiant disorder	12.4%
Anxiety disorder	17.1%

Key: ADHD, attention-deficit/hyperactivity disorder.

directed at many aspects of the child's life—education, social and recreational activities, behavior problems, and associated impairments (Shapiro & Batshaw, 2016; Wehmeyer et al, 2017). Support for parents, siblings, and other caregivers (both family members and unrelated caregivers) is also important (see textbox titled Cultural Competence and Intellectual Disability, along with Chapter 37).

Educational Services

Education is the single most important discipline involved in intervention for children with intellectual disability and their families (see Chapters 31 and 33). The achievement of good outcomes in an educational program is dependent on the interaction between the student and teacher. Educational programs must be relevant to the child's needs and address the child's

CULTURAL COMPETENCE AND INTELLECTUAL DISABILITY

In caring for individuals with intellectual disability, it is important to be sensitive to cultural issues that can affect care. It can be generally assumed that parents love their children and want what is best for them. However, as professionals, we cannot assume that all families will attempt to achieve an optimal outcome for their child in the same way, and the culture they live in may present challenges. In some cultures, the visible presence of a child with a disability may adversely impact the marriage prospects of other children in the family. The family may thus want to homeschool the child or have him or her in a segregated school. In other cultures, traditional rather than modern medicine may be practiced, which may affect the use of needed medication or surgery. The practitioner who does not understand and respect the culture that defines the family may lose the opportunity to continue caring for the child. Therefore, it is essential to understand and respect the cultural background that may define the families with whom you work. It is often possible to work within these confines and still provide excellent and respectful care.

BOX 14.2 INTERDISCIPLINARY CARE**The Special Education Teacher**

Perhaps the most important discipline in caring for a child with intellectual disability is special education. The special education teacher is essential in designing and then carrying out the individualized family service plan (IFSP; for early intervention) or individual education program (IEP; for primary and secondary school). The teacher is the hub of care for the child with intellectual disability, bringing in other disciplines as needed to assist in developing an effective learning environment. The teacher is trained in both pedagogical techniques and behavior management for children with special education needs and is also tasked with assessing the progress of the child educationally and revising the curriculum as needed to optimally serve the student.

individual strengths and challenges. The child's developmental level and his or her requirements for support and goals for independence provide a basis for establishing an IFSP in early intervention programs and an IEP in school programs (see Box 14.2).

It should also be remembered that learning begins at home in the context of a child's family. Early intervention for infants and toddlers (birth to 3 years) usually takes place in the home as well. The home continues to be the primary educational setting for 3 to 4 year olds, although many children attend out-of-home center-based or preschool programs. At age 5, most children enter kindergarten for half- or full-day sessions and are introduced to a more formal learning environment. Formal special education services are provided in the school setting thereafter.

Leisure and Recreational Needs

In addition to education, the child's physical, social, and recreational needs should be addressed (Andrews, Falkmer, & Girdler, 2015; Patel & Greydanus, 2010; Vondra, de Witte, Reichrath, Buntinx, & Curfs, 2009; Wehmeyer et al., 2017). Peer socialization in play and recreational activities constitutes an important part of social-emotional development and builds resilience. As such, socialization competencies and experiences (e.g., dealing with social conflict, managing anger, making needs known, and expressing affection or unhappiness) can exert a significant influence upon developmental outcomes and school readiness and participation and can eventually influence future success in adult life. In the ideal world, children with intellectual disability would participate as equals in all recreation and leisure activities. Although young children with intellectual disability are not usually excluded from play activities, parents still may have a difficult time finding age- and skill-appropriate adaptive play equipment (cost can be a significant factor) or socially oriented play groups

(transportation costs and availability of inclusive programs are additional compromising factors). Furthermore, adolescents with intellectual disability are often not included by their typically developing peers in extracurricular sports and social activities. Yet, participation in sports or related exercise regimens should be encouraged with all children, as functionally appropriate, because it offers many immediate and long-term benefits, including weight management, development of physical coordination, maintenance of cardiovascular fitness, and improvement of self-image. For some individuals, these needs can be met through the Special Olympics.

Social activities are equally important to the social and emotional development of youth with intellectual disabilities. Such activities should include those with adolescents of the opposite gender and with typically developing youth. These activities, however, need to be based on the youth's functionally adaptive and age-appropriate behaviors. Examples of normalizing activities include participation in summer camps; school dances; school or family trips; dating or socialization in youth groups or school clubs; visits to movies, restaurants, and other socializing establishments; and other typical recreational events. These activities should also include opportunities for increasing social-emotional independence away from direct parental oversight. They should additionally involve exposure to novel experiences in which the individual has the opportunity to test, grapple with, and practice his or her overall adaptive competencies (see Chapter 40). While parental oversight may diminish during this period, sufficient supports are needed to ensure that the adolescent with intellectual disability is not targeted, bullied, or taken advantage of in these settings.

Behavior Therapy

Although most children with intellectual disability do not have behavior disorders, behavior problems do

occur with a greater frequency in this population than among children with typical development (Munir, 2016). To facilitate the child's socialization and to avoid limiting academic opportunities, significant behavior problems must be addressed (see Chapter 34). Behavior problems may result from associated neurodevelopmental disorders (e.g., ADHD or sensory disorders); primary or secondary psychiatric disorders (e.g., mood disorders); unrealistic parental expectations; family, financial, or social difficulties; and school-related adjustment difficulties (Deutsch, Dube, & McIlvane, 2008). Many behavior problems result from a mismatch between the demands of the situation and the child's abilities. Often, behavior problems represent attempts by the child to communicate, gain attention, or avoid performing a task. In assessing problematic behavior, one must first consider whether a behavior is appropriate for the child's "cognitive" age rather than for his or her chronological age. The child's chronological age, however, needs to be considered when addressing behavioral challenges in real-life settings. An environmental change, such as a more appropriate classroom, may improve behavior problems for some children; for others, behavior management techniques (see Chapter 34) or the use of psychotropic medication may be appropriate.

Treatment of Comorbid Conditions

Comorbid conditions must be addressed to achieve an optimal outcome for the individual with intellectual disability. Comorbid conditions include, for example, cerebral palsy; sensory impairments; seizure disorders; speech disorders; ADHD; anxiety disorders; depression; ASD; and other disorders of language, behavior, or perception. Treatment of comorbid conditions may require ongoing physical therapy, occupational therapy, speech-language therapy, behavioral therapy, adaptive equipment, eyeglasses, hearing aids, medication, and so forth. Failure to adequately identify and treat these problems may negatively influence functional outcomes and result in difficulties in the home, school, or neighborhood environment.

Use of Medication

Medication is not useful in treating the core symptoms of intellectual disability; no drug has been found to improve cognitive function in these individuals. Medication may be helpful, however, in treating comorbid behavioral and emotional disorders (McQuire, Hasiotis, Harrison, & Pilling, 2015; Risen, Accardo, &

Shapiro, 2010). These drugs are generally directed at specific symptom complexes, including ADHD (e.g., stimulants and alpha-2-adrenergic agonists), self-injurious behavior or aggression (e.g., mood stabilizers and neuroleptics), and mood or obsessive-compulsive disorders (e.g., selective serotonin reuptake inhibitors). The properties of these psychopharmaceutical drugs are outlined in Chapter 38. Before long-term therapy with any drug is initiated, a short trial should be conducted. Even if a medication proves successful, its use should be reevaluated at least yearly to assess the need for continued treatment.

Family Counseling

All families benefit from anticipatory guidance regarding their child's health and development, and this is especially true for those families who have children with intellectual disability (Coren, Hutchfield, Thomae, & Gustafsson, 2010). Many families adapt well, but some have significant emotional challenges. Among the factors that have been associated with family coping skills are the severity of the child's disability, number of siblings, stability of the parents' relationship, parental age, mental and physical health of the family, financial stability, expectations and acceptance of the child's diagnosis, supportiveness of the extended family, and availability of community resources and respite care services. In families in which the emotional demands of having a child with intellectual disability are great, family counseling and sibling support groups should be an integral part of the treatment plan (Crnic, Neece, McIntyre, Blacher, & Baker, 2017; see Chapter 37).

Periodic Reevaluation

Since the needs of children and their families change over time, a child's health, learning, and adaptive and behavioral goals must be reassessed periodically, and management programs must be adjusted accordingly. A periodic review should include information about the child's health status as well as his or her functioning at home, at school, and in other social contexts. Other evaluations, such as formal **psychoeducational** testing, may be needed (see Chapter 13). Reevaluation should be undertaken at transition points, at any time the child is not meeting expectations, and when he or she is moving from one service provision system to another. Reevaluations are needed during early childhood and preschool years to ensure that the program remains appropriate as the child matures.

Children with intellectual disability and their families experience many transitions. Among the predictable transition points are 1) from recognition to identification, 2) from identification to diagnosis, 3) from diagnosis to intervention, 4) from intervention to primary education, 5) from early elementary school to later elementary school, 6) from elementary to middle school, 7) from middle school to high school, and 8) from high school to post high school (including specialized college program for individuals with ID).

Transition programs for typical adolescents center on the move from pediatric to adult health services. For adolescents with intellectual disability (and other developmental disabilities), this transition is more complex. IDEA (2004) requires that all students with an individualized education program begin transition planning before the student is 16 years old and that the plan is based on the student's individual needs, strengths, skills, and interests (see Chapter 33). Among the domains that should be addressed in a complete transition plan are 1) self-determination and decision making, 2) transition of health care (including needed therapies), 3) transition of mental health services, 4) home living, 5) community living, 6) continuing education, 7) employment, 8) leisure and socialization, 9) protection from exploitation, and 10) legal (including parental wills, estate planning, and trusts) services (Neece, Kraemer, & Blacher, 2009; Seo, Shogren, Wehmer, Little, & Palmer 2017).

Additional factors that complicate transition into adulthood for individuals with intellectual disability are the termination of the entitlement to education and related services afforded by IDEA and a lack of availability of case management services that help coordinate across therapeutic domains.

OUTCOME

Except for individuals with severe-profound intellectual disability, IQ scores alone are not good predictors

of outcome. Outcome instead depends on the interplay of many factors including 1) the underlying cause of the intellectual disability; 2) the degree of functional disability; 3) the presence of comorbid conditions (such as epilepsy) and behavior problems; 4) the capabilities of the family; and 5) the supports, community services, and training provided to the child and family (Patel, Greydanus, Calles, & Pratt, 2010).

As adults, many people with mild intellectual disability are able to gain functional literacy and some economic and social independence and only require intermittent supports (Seltzer et al., 2009). Adults with mild intellectual disability show impairments in abstract thinking, executive function, short-term memory, and functional academics. Communication, conversation, language, and social judgement may be more immature than expected for age, and limited understanding of risk in social situations is common (APA, 2013). Support for health care decisions and legal matters is often required. Such adults may need periodic assistance, especially when under social or economic stress. Some marry and live successfully in the community, either independently or in supervised settings (Felce et al., 2008). Life expectancy usually is not adversely affected.

For individuals with moderate intellectual disability, the goals of education are to enhance adaptive abilities, functional academics, and vocational skills to ensure that these individuals are better able to live in the adult world (Totsika, Felce, Kerr, & Hastings, 2010). Academic skill development is typically at an elementary school level. Social and communicative behavior is markedly different from typical peers, but enduring friendships may be established. Personal care and household tasks require instruction, and reminders may be needed. Contemporary gains, including supported employment, have benefited these individuals the most. Supported employment challenges the view that prerequisite skills must be taught before there can be successful vocational adaptation. Instead, individuals are trained by a coach to do a specific job in

ETHICAL CONSIDERATIONS

The rights of an individual with intellectual disability have not always been considered in our society, and this was an ethical failure. Individuals with intellectual disability were segregated in schools for the "retarded"; they were deprived of advanced medical care (such as transplants), experimented on without their consent, and their civil rights were not respected (sterilization). Fortunately, the civil rights movement in the 1960s also benefited people with disabilities. There was the integration of children with disabilities into typical classes, the requirement of consent by the individual (or primary caregiver) for medical or research procedures, and the provision of other basic rights that all citizens should have.

the setting in which the person works. This approach bypasses the need for extended time mastering “prerequisite skills” and has resulted in successful work adaptation in the community for many people with intellectual disability. Outcome studies have documented the benefits and effectiveness of this approach (Stephens, Collins, & Dodder, 2005). People with intellectual disability requiring limited support (e.g., individuals with Down syndrome) generally live at home or in a supervised setting in the community.

As adults, people with severe to profound intellectual disability require extensive to pervasive support in activities of daily living, decision making, and communication. They may, however, perform simple tasks in supervised settings. These individuals often have comorbid conditions such as cerebral palsy, seizure disorders, and sensory impairments that further limit their adaptive functioning, yet most people with this level of intellectual disability are able to live in the community with supportive adaptations in their environment and with supervisory oversight. Family-based, community-supported care is preferable to institutional care for these individuals, but it is often difficult to achieve for a variety of reasons (e.g., parents’ advanced ages, lack of financial support, familial or community resistance, and comorbid conditions). As a result, some of these individuals with severe medical problems, major behavioral disturbances, or disrupted families require out-of-home living in such settings as foster homes, alternative living units, group homes, nursing homes, or residential schools. People who require extensive or pervasive supports have increased utilization of medical and behavioral health care and often have a shortened life span (Kilgour, Starr, & Whalley, 2010).

SUMMARY

- Development is an ordered process that is linked to the maturation of the central nervous system.
- With intellectual disability, development is altered so that intellectual and adaptive skills are impaired.
- In most cases of mild intellectual disability, the underlying cause is unclear and may be tied to environmental effects.
- In individuals with severe intellectual disability there is usually a definable biologic, often genetic, cause.
- Most people with intellectual disability have a mild degree of impairment, require only intermittent support, and are often able to achieve some degree of economic and social independence.
- The early identification of a global developmental delay is important to ensure appropriate treatment and to enable the child to develop and use all of his or her capabilities.
- Treatment should be multimodal, supporting the education, mental and physical health, adaptive behavior, and communication skills of individuals with intellectual disability.

CHAPTER 15

Down Syndrome and Fragile X Syndrome

Elizabeth Berry-Kravis, Katherine Myers, and Nancy J. Roizen

After completion of this chapter, the reader will

- Recognize the physical characteristics of Down syndrome
- Be aware of the substantial increase in life expectancy in individuals with Down syndrome
- Identify the health issues that are common in children with Down syndrome
- Appreciate the increased incidence of autism in children with Down syndrome
- Know the clinical differences between a premutation and full mutation for fragile X syndrome
- Be alert to the physical findings of fragile X syndrome
- Be able to identify the clinical presentation of fragile X syndrome
- Have an approach to treating the medical and behavioral problems found in fragile X syndrome

Down syndrome (DS) is the most common chromosomal **etiology** (cause) of intellectual disability, while fragile X syndrome (FXS) is the most common inherited form of intellectual disability (ID). In this chapter, DS and FSX are discussed in depth because they are associated with multiple medical problems, as well as behavior challenges that require identification and intervention.

DS was one of the first symptom complexes associated with ID to be identified as a syndrome. In 1866, Dr. John Langdon Down, for whom the syndrome is named, published the first complete physical description of DS, which included a similarity of facial features

among affected individuals (Down, 1866). Nearly 100 years later, in 1959, researchers identified the underlying chromosomal abnormality—an additional chromosome 21—that causes DS (Lejeune, Gautier, & Turpin, 1959). More recently, in 2000, an international collaborative group of scientists completed the genomic sequence of HSA21q (the long arm of chromosome 21, which accounts for the findings of the syndrome) (Hattori et al., 2000).

FXS is the most common cause of X-linked ID (Lubs, Stevenson, & Schwartz, 2012). It was initially identified in 1943, when Martin and Bell described a family with 11 males across two generations with

an X-linked form of ID, which came to be known as Martin-Bell syndrome (Martin & Bell, 1943). In 1969, researchers developed a cytogenetic (chromosome) test that identified a break or constriction of a region of the X chromosome, which was initially referred to a “marker X” and was later referred to a “fragile X” (Lubs, 1969). In 1991, a gene associated with multiple CGG nucleotide repeats was identified that coincided with the fragile X site. It was named the *fragile X mental retardation 1* [*FMR1*] gene and became the basis of a new, more accurate test for FXS (Verkerk et al., 1991). In 2001, a fragile X-associated tremor/ataxia syndrome was discovered (FXTAS; Hagerman et al., 2001).

■ ■ ■ CASE STUDY

Jerome is a 13-year-old boy with DS. He experiences complex behavioral problems as well as bilateral mild to moderate hearing loss, obesity, sleep apnea, enuresis (lack of urinary control), refractive errors, and mild gastroesophageal reflux disease (*GERD*). On psycho-educational testing at 6 years of age, he had a full-scale intelligence quotient (IQ) of 50. ADHD was diagnosed and he began stimulant medication, which helped with inattention and impulsivity. By 8 years of age, all observers reported anxiety with transitions, panic attacks, and melt downs with aggression at school, which improved with a selective serotonin reuptake inhibitor (SSRI). However, by 10 years of age he was not functioning well at school, and his family moved him to a state-developed home-school program. He is functioning well with counseling, medication, as well as careful management of social opportunities. Now, at 14 years of age, there are issues with medical treatment. Fortunately, his hearing loss has not progressed, but Jerome refuses to wear his hearing aids. His obesity has increased. Sleep apnea improved with tonsillectomy and adenoidectomy. His enuresis (urinary incontinence) was treated with medication and has resolved. He wears glasses. His GERD has also resolved.

■ ■ ■ CASE STUDY

James is a 20-year-old young man who had an uneventful birth, delayed early motor development, and a mild strabismus (weak eye muscles) noted in the first year of life that was managed with patching and glasses. He walked at 15 months; was able to say only a few words by age 2; and had recurrent ear infections, which were initially thought to be the cause of his language delay. The delay persisted after myringotomy tube placement (see Chapter 26), however, and he did not talk in phrases until age 4. He was treated with speech and occupational therapy and evaluated for developmental delay by

a specialist, who noted him to have flat feet but otherwise unremarkable physical features. Subsequent testing of cognitive and adaptive skills confirmed that James had moderate ID. Genetic testing revealed an *FMR1* full mutation consistent with a diagnosis of FXS. Behavior became very hyperactive around age 3, and he was hypersensitive to sounds and had tactile defensiveness. His attention ability was limiting at school, and so at age 5 he was started on stimulant medication, which improved his ability to stay at his seat and be on task. He performed at about half his age level at school, with particular problems with writing and math, but he had better, though still delayed, visual memory and reading skills. He had a special education program with partial inclusion through high school. He was better able to control hyperactive behavior as he became older, but by high school age, he was anxious about performing school work, resisted going out to do new things, did not like crowds, and seemed to be more reclusive. He would sometimes become upset and aggressive when things did not go his way. His anxiety and aggression were improved with treatment with an SSRI (see Chapter 27), which also allowed better ability to participate in his vocational training at job sites.

Thought Questions:

How do children with DS compare to those with FXS in factors of genetics, behavioral issues, and ID? How are medical complications similar for children with DS and FXS?

DOWN SYNDROME

Prevalence

DS is the most common chromosomal abnormality diagnosed in the United States. With increased births to older mothers and elective terminations of pregnancies, the overall birth prevalence has been steady at about 1 in 700 births. With advances in medical care, the median life expectancy has increased from 4 years in 1950 to 58 years in 2010 (de Graaf, Buckley, & Skotko, 2015).

Physical Characteristics

The distinct physical features of DS include 1) low muscle tone (infants appear “floppy”); 2) flat facial features with a small nose; 3) an upward slant to the eyes; 4) small skin folds on the inner corner of the eyes; 5) small, atypically shaped ears; and 6) a single deep crease across the center of the palm (Jones, Jones, & del Campo, 2013). Medical complications affect almost

every body organ system and are described in greater detail below (Bull & American Academy of Pediatrics Committee on Genetics, 2011). They include congenital heart defects; endocrine abnormalities; sensory impairments; growth and obesity problems; dental concerns; gastrointestinal (GI), renal, and urinary tract abnormalities; epilepsy; hematologic disorders; and skin conditions. In addition, there are cognitive deficits, including mild to moderate ID and a later risk of Alzheimer disease, and neurobehavioral issues.

Chromosomal Findings

DS occurs due to chromosomal abnormalities in chromosome 21. Specifically, three types of abnormalities result in extra copies of the DS area of chromosome 21: Trisomy of chromosome 21 accounts for approximately 94% of the cases, translocation for 4.3%, and mosaicism for 2.1% (Jones et al., 2013; see Chapter 1).

Medical complications occur with similar frequency in the three types of the chromosomal abnormalities. Studies indicate that children with translocation DS do not differ cognitively from those with trisomy 21. By contrast, children with mosaic DS, perhaps because not all cells are affected, on average score higher on IQ tests than those with trisomy 21 or translocation DS (Fischler & Koch, 1991).

Early Identification

The American College of Obstetricians and Gynecologists recommends that all pregnant women should be offered screening before 20 weeks' gestation and diagnostic testing for DS if desired (Carmichael et al., 2017; Gill, Quezada, Revello, Akolekar, & Nicolaides, 2015; see Chapter 3). After birth, if there are signs of DS, diagnosis can be evaluated by chromosome analysis (karyotype) of the blood. Common signs in more than 75% of newborns include oblique (slanted) palpebral fissures (eye openings), a wide space between the first and second toes, increased neck tissue, hypotonia (low muscle tone), and a flat facial profile (Jones et al., 2013).

Medical Problems

Children with DS have an increased risk of abnormalities in almost every organ system (Bull & American Academy of Pediatrics Committee on Genetics, 2011). Knowledge of these possible medical complications enables the health care provider to evaluate the child for the more common conditions (e.g., congenital heart malformation, hearing problems, vision problems, and obstructive sleep apnea). Health care providers should also monitor, (e.g., thyroid problems, hemoglobin, and growth), prevent (e.g., gingivitis and obesity), and be vigilant for symptoms of other medical problems (e.g., diabetes and urological abnormalities). There is a risk for **diagnostic overshadowing** (presuming that symptoms are simply a consequence of the DS) that can lead to postponing or missing a diagnosis. DS clinics with physicians and other professionals involved in the care of children and adults with DS can help evaluate concerns and problems, taking into consideration the contribution of medical, behavioral, and developmental factors (Box 15.1).

Obstructive Sleep Apnea and Airway Concerns

Obstructive sleep apnea is when breathing intermittently stops when the airway is blocked. Symptoms include snoring, apnea, restless sleep, daytime sleepiness, frequent night awakenings, and behavior problems. Although pneumonia and other airway problems are not usually considered in the system review in children with DS, they are the most common reason for children with DS to be admitted to the hospital and the leading cause of excess mortality (McDowell & Craven, 2011).

Hearing Problems

As many as 26% of newborns with DS fail their newborn hearing screen, and after diagnostic evaluation the prevalence of congenital hearing loss is estimated at 15%–20% in newborns (Tedeschi et al., 2015). In addition, children with DS who pass their newborn hearing screen can still develop conductive, sensorineural, and mixed hearing loss (see Chapter 26).

BOX 15.1 INTERDISCIPLINARY CARE

The Clinic Coordinator

For a Down syndrome clinic, the clinic coordinator, often a social worker or a nurse, is the person who helps parents keep track of the needed evaluations, monitoring, their outcomes, and follow-ups so that the parents are supported in their pursuit of optimal care for their child.

In school-age children, 22%–30% experience transient hearing loss with frequent **otitis media** (OM) and 24.9% have a permanent hearing loss, most frequently bilateral (75.4%) and conductive (33.3%) (Nightengale, Yoon, Wolter-Warmerdam, Daniels, & Hickey, 2017).

Vision Problems Deficits in **visual acuity** (near-sightedness or farsightedness) occur in 30%–62% of DS cases, with **amblyopia** (loss of vision with brain suppressing vision) occurring in 3%–20% of cases of DS. Other eye conditions like **strabismus** (crossed eyes; 20%–60%) and **nystagmus** (jiggling of the eyes; 10%–20%), as well as cataracts, are also found more frequently than in the general population (Creavin & Brown, 2009; Roizen, Mets, & Blondis, 1994).

Congenital Heart Defects In children with DS, 44% have congenital heart defects, the most common being **endocardial cushion defect** (resulting in connection between the two upper chambers, or atria, of the heart and the two lower chambers, or ventricles, of the heart; 30%), followed by **atrial septal defect** (connection between the two upper chambers; 25%), and **ventricular septal defect** (a connection between the two lower chambers; 22%) (Stoll, Dott, Alembik, & Roth, 2015).

Dental Problems The most serious dental problem common among children with DS is early-onset **periodontal disease** (disease of tissue surrounding the gums), which involves **gingivitis** (gum inflammation) and regression of the bone that anchors the teeth. In addition, children with DS are more likely than their healthy peers to have delayed eruption and **malocclusions** (abnormal contact of opposing teeth). Many individuals with DS have dental anomalies (e.g., fused teeth; **microdontia**, or small teeth; and missing teeth) and **bruxism** (teeth grinding). Interestingly, children with DS are less affected by dental **caries** (cavities) than are typically developing children (58% versus 78%; Dieguez-Perez, de Nova-Garcia, Mourelle-Martinez, & Bartolome-Villar, 2016).

Thyroid Disease Newborns with DS have an increased prevalence of congenital hypothyroidism (in-born deficiency of thyroid hormone production) resulting from impaired development of the thyroid gland. Hypothyroidism needing supplemental thyroid therapy has been identified in 17.5% of newborns (Purdy, Singh, Brown, Vangala, & Devaskar, 2014). The incidence increases with age, with perhaps 24% having a thyroid disorder by 10 years of age and 50% by

adulthood (Iughetti et al., 2014; Pierce, Fanchi, & Pinter, 2017). Although hypothyroidism predominates, hyperthyroidism (excess thyroid hormone production) associated with Hashimoto's thyroiditis (an inflammatory condition of the thyroid gland) is also found.

Seizures and Neurological Problems Children with DS are at risk for a variety of neurologic problems, including seizures and strokes. A survey of more than 350 children and adolescents with DS revealed epileptic seizures in 8%, of which 47% were partial seizures, 32% were infantile spasms, and 21% were generalized tonic-clonic seizures (Goldberg-Stern et al., 2001; see Chapter 22). Moyamoya disease (blocked arteries at the base of the brain) is a rare progressive disorder that is associated with strokes. Of children less than 15 years of age admitted to the hospital with moyamoya, 9.5% have DS (Kainth, Chaudhry, Kainth, Suri, & Qureshi, 2013).

Celiac Disease and Gastrointestinal Problems GI problems are increased in DS and include celiac disease, constipation, congenital GI malformations, and gastroesophageal reflux. **Celiac disease**, sensitivity to wheat and other grains, is reported in at least 5% of children with DS (Szaflarska-Popolawska et al., 2016). Congenital GI malformations are found in 6% of children with DS, most frequently presenting in the newborn period with poor feeding, vomiting, or aspiration pneumonia. The most common malformations are **duodenal** (first section of the intestine) stenosis (narrowing) or **atresia** (blockage) (67%); imperforate (closed) anus (14%); and Hirschsprung disease (lack of innervation of the colon; 14%) (Stoll et al., 2015).

Obesity and Growth Although children with DS are proportional at birth, they frequently become lighter for their height initially and then gain proportionally more weight compared with height. Eventually 47.8% develop obesity (defined as a body mass index [BMI] greater than 95%) compared with 12.1% in a community sample (Basil et al., 2016). There can also be problems with poor gain in weight and/or height related to medical conditions like congenital heart failure or celiac disease.

Leukemias and Anemia Leukemias are the most common cancer in children with DS and account for 97% of all malignancy in children with DS 15 years of age or younger. Individuals with DS have a 10- to 20-fold higher relative risk than the general population, with a cumulative risk of 2% by 5 years of age (Rabin & Whitlock, 2009). Children with DS have low dietary

intake of iron (Luke, Sutton, Schoeller, & Roizen, 1996). Iron deficiency or iron deficiency anemia are found in 10% of this population (Dixon et al., 2010).

Orthopedic Problems Orthopedic problems can be painful and interfere with function. Problems include hip subluxation (instability and dislocation of the hip joint), **patellar** (knee cap) and other joint instability, and **pes planus** (flat feet). The most perplexing and potentially serious problem is **atlantoaxial instability** (partial subluxation of the upper spine; Figure 15.1), which occurs in 10%–30% of individuals with DS as a result of atlanto-occipital and atlantoaxial hypermobility; about 2% of these are symptomatic (Bull & American Academy of Pediatrics Committee on Genetics, 2011).

Other Frequent Medical Problems Children with DS also may experience type I diabetes, rheumatoid arthritis, alopecia (hair loss), vitiligo (loss of pigment in skin), testicular cancer, and urologic and renal disorders. In children with DS, type I diabetes has a 4.2-fold increased prevalence compared with the general population (Bergholdt, Eising, Nerup, & Pociot, 2006;

Whooten, Schmitt, & Schwartz, 2017). Juvenile idiopathic arthritis is six times higher than in the general pediatric population and is associated with joint subluxation in half of the cases. The average delay from symptom onset to diagnosis is 2 years (Juj & Emery, 2009); this is a good example of diagnostic overshadowing. Testicular cancer is the only solid tumor in DS with an increased incidence (Hasle, Friedman, Olsen, & Rasmussen, 2016). The spectrum of renal and urologic malformations occurs in 3.2% of the DS population, with an odds ratio of 4.5 compared with the general population (Kupferman, Cruschel, & Kupchik, 2009).

Evaluation and Treatment of Medical Complications

Since children with DS may have increased risk for medical problems, as discussed above, medical providers must ensure that they are engaging in evaluation, screening, and prevention for common conditions. They must remain vigilant for symptoms of these or other medical complications throughout their work with children with DS. Recommendations for preventive health care for children and adolescents with DS are outlined below and summarized in Figure 15.2.

Figure 15.1. Children with DS are at risk of developing subluxation (partial dislocation) of the atlantoaxial or atlanto-occipital joint, as shown in this illustration (right side). A typical neck region is shown for comparison (left side). This subluxation predisposes these children to spinal injury with trauma. This abnormality can be detected by X-ray or an MRI scan of the neck.

	Birth to 1 month	Infancy months						Early childhood years					Late childhood years									
		2	4	6	8	10	12	1	2	3	4	5	5	7	9	11	13	13	15	17	19	21
Karyotype	•																					
Echocardiogram	•																					
Hearing screen and follow-up	•																					
Audiological ¹				•				Every 6 months														
Ear specific audiogram ¹													Annually									
Eye exam for cataracts ²	•																					
Ophthalmology referral		Once in 1st 6 mo						Annually					Every 2 years					Every 3 years				
TSH (Thyroid Stimulating Hormone)	•			•			•	Annually														
CBC ³ (complete blood count) and differential	•																					
Hb ⁴ (hemoglobin)								Annually														
Hb only																		Annually				
Radiographic swallowing assessment ⁵	If symptomatic																					
Lateral neck x ray in neutral position ⁶	If symptomatic																					
Tissue transglutaminase IgA and quantitative IgA ⁷								If symptomatic														
Echocardiogram ⁸																		If symptomatic				

1. If normal hearing established, do behavioral audiogram and tympanometry until bilateral ear specific testing possible. Refer child with abnormal hearing to otolaryngologist.

2. Referral to ophthalmologist who has experience with Down syndrome to assess for strabismus, cataracts, and nystagmus.

3. To rule out transient myeloproliferative disorder; polycythemia.

4. Hb annually; CRP (c-reactive protein) and ferritin or CHr (reticulocyte hemoglobin content) if possible risk of iron deficiency or Hb < 11 g.

5. If marked hypotonia, slow feeding, choking with feeds, recurrent or persistent respiratory symptoms, failure to thrive.

6. If myelopathic symptoms: obtain neutral position spine films and, if normal, obtain flexion and extension films and refer to pediatric neurosurgeon or orthopedic surgeon with expertise in evaluation and treating atlanto-axial instability.

7. If symptoms of celiac disease are present.

8. If symptoms of acquired mitral or aortic valve disease such as increased fatigue, shortness of breath, or exertional dyspnea or abnormal physical examination findings such as a new murmur or gallop.

Figure 15.2. Recommendations for preventive health care for children and adolescents with Down syndrome. (Source: Bull & American Academy of Pediatrics Committee on Genetics, 2011.)

Obstructive Sleep Apnea: Evaluation and Symptomatic Vigilance

In light of the high incidence of sleep apnea, the American Academy of Pediatrics (AAP) recommends a sleep study for all children with DS by 4 years of age regardless of whether they have symptoms of sleep apnea. First-line treatment is usually tonsillectomy with and without an adenoidectomy, which decreases symptoms in 50% of individuals but has a low cure rate (17%–20%; Nation & Brigger, 2017). Continuous positive airway pressure with a mask is sometimes possible and effective, but it is uncomfortable. Newer interventions include tongue reduction and other surgery at the base of the tongue. Hypoglossal nerve stimulator implantation is presently in a multicenter trial (Bassett & Musso, 2017; Diercks et al., 2018). Obstructive sleep apnea is associated with lower IQ and behavior problems and eventually can lead to heart failure (Lott & Dierssen, 2010). See Box 15.2 for more information on obstructive sleep apnea and DS.

Hearing Problems: Evaluation After newborn screening for hearing loss (see Chapter 7), the AAP health supervision guidelines recommends hearing screening starting at 6 months of age and every 6 months to 5 years of age and then annually (Bull & American Academy of Pediatrics Committee on Genetics, 2011). Treatment for hearing loss commonly includes surgical placement of pressure equalization tubes (PET; Bernardi, Pires, Oliveria, & Nisihara, 2017; Manickam, Shott, Heithaus, & Shott, 2016) and less frequently hearing aid use (Yaneza, Hunter, Irwin, & Kubba, 2016) and cochlear implants (Phelan, Henderson, Green, & Bruce, 2016). Of school-age children, 23% used hearing aids or had them recommended in a treatment plan (Nightingale et al., 2017). In a 15-year longitudinal study from infancy of 57 children with DS who were consistently monitored for hearing loss, PET placement occurred in 88.8%, normal hearing was present in 38%–44%, and tympanic membrane perforations were present in 17% of ears (Manickam et al., 2016).

Vision Problems: Evaluation The AAP recommendation is for infants with DS to be evaluated by an ophthalmologist experienced with children by 6 months of age, or sooner if there are any concerns. Unless more frequent visits are indicated, follow-up evaluations are recommended to occur annually from 1 to 5 years of age, then every 2 years from 5 to 19 years of age, and then every 3 years from 13 to 21 years of age.

Cardiac: Evaluation An echocardiogram is recommended for the newborn with DS, even if there has been a prior fetal echocardiogram (Bull & American Academy of Pediatrics Committee on Genetics, 2011). Data indicate that children with DS have a similar rate of mortality as do other children with the same heart defect (Fudge et al., 2010). Since the early 2000s, there has been a trend toward increased use of invasive therapy, including corrective or palliative cardiac surgery and therapeutic catheterization, in children less than 12 months of age (Dias et al., 2016). In a cross-sectional study of children with DS, the parents of children with congenital heart disease reported that 55% needed cardiac surgery at a mean age of 9.6 months (Roizen et al., 2014).

Dental: Monitoring Children with DS need early and regular dental care to prevent and limit the development of gingivitis, which eventually can lead to loss of teeth. Arguably, all children with DS need orthodontic treatment for their malocclusion (Andersson, Axelsson, & Katsaris, 2016), but not all can tolerate the discomfort.

Thyroid: Monitoring As with all newborns, infants with DS are routinely screened for thyroid dysfunction. The initial screen should include a thyroid-stimulating hormone (TSH). Follow-up TSH screening should occur at 6 and 12 months of age and then continued annually (Bull & American Academy of Pediatrics Committee on Genetics, 2011; Whooten et al., 2017). More frequent

BOX 15.2 EVIDENCE-BASED PRACTICE

Obstructive Sleep Apnea and Down Syndrome

In a study of 3-year-olds with Down syndrome (DS) chosen for having normal hearing and followed from infancy, at least 57% had evidence of obstructive sleep apnea when evaluated by **polysomnograms** (i.e., a sleep study). Of the 69% of parents who reported no sleep problems in their child with DS, 54% of their children were found to have abnormal sleep study results (Shott et al., 2006). This study increased awareness of the frequency of obstructed sleep apnea in preschoolers with DS and the need to identify it and develop interventions that work.

TSHs are indicated if the child displays plateauing height, behavior problems, or an unexpected lack of cognitive progress (Lott & Dierssen, 2010). If there is clinical and laboratory evidence of thyroid disease, treatment is indicated.

Seizures and Other Neurological Problems: Vigilance

When comparing children with and without DS who develop infantile spasms (see Chapter 22), the median age of diagnosis (6–7 months) and time from diagnosis to treatment (1.0 day) does not differ, nor is there a difference in treatment timelines. Compared with other children with **idiopathic** (no-identified-cause) infantile spasms, children with DS appear to be more responsive to treatment (Beatty, Wrede, & Blume, 2017). Children with infantile spasms and associated neurological insults are more likely to progress to epilepsy.

Celiac and GI Problems: Symptomatic Vigilance

Presenting symptoms of celiac disease can include abdominal pain, constipation, diarrhea, failure to thrive, reflux, vomiting, short stature, and fatigue (Khatib, Baker, Ly, Kozielski, & Baker, 2016). The AAP recommended health supervision for children with DS who have symptoms of celiac disease is screening with blood tissue transglutaminase immunoglobulin A (IgA) and quantitative IgA (Bull & American Academy of Pediatrics Committee on Genetics, 2011). Medical evaluation and treatment are recommended for constipation unresponsive to dietary intervention, signs of a bowel obstruction, or GE reflux.

Obesity and Growth: Monitoring and Prevention

Several factors contribute to the development of obesity in DS, including a lower resting metabolic rate (Luke, Roizen, Sutton, & Schoeller, 1994), decreased activity level, and preferring indoor activities compared with siblings. In 2015, updated growth charts for children and adolescents with DS were published for monitoring growth (Zemel et al., 2015). The recommendation is that for children with DS who are 10 years of age or older, the Centers for Disease Control (CDC) BMI growth chart 85th percentile is a better indicator of excess adiposity (100% sensitivity) than the new DS-specific BMI charts, which have low sensitivity (62.3%; Hatch-Stein et al., 2016; Whooten et al., 2017).

Leukemias: Vigilance Signs of leukemia include bruising due to low platelets, fatigue due to anemia, and frequent or unusual infections, and these should be evaluated given the increased risk of leukemia in DS.

With the newest treatment trials, myeloid leukemia in DS has an 89.9% 5-year event-free survival rate and an overall survival rate of 93% for the majority of children, but for less than 10%, the leukemia is refractory and relapses, with a 5-year overall survival rate of 34.4% (Taub et al., 2017). For acute lymphoblastic leukemia, on contemporary protocols, the outcomes for children with DS continue to be poorer than for children without DS, with a 5-year event-free survival rate of 65.6% for children with DS compared with 87.7% for children without DS and an overall survival rate of 70% for children with DS compared with 92.2% for children without DS (Patrick et al., 2014).

Orthopedic Problems: Vigilance

Symptoms of atlantoaxial instability include new neck pain, torticollis (stiff neck), loss of motor skills such as limping, loss of bowel or bladder control, having new difficulty climbing stairs, or any neurological changes. Parents should be advised to have their child seen urgently by a physician the day that the symptoms are first noticed. The child needs plain lateral cervical spine radiography (a side-view neck x-ray) in the neutral position. If there are any abnormalities, the child should be immediately referred to a pediatric neurosurgeon or orthopedic surgeon experienced in the evaluation and treatment of atlantoaxial instability (Bull & American Academy of Pediatrics Committee on Genetics, 2011).

Development and Behavior

Intellectual disability (see Chapter 14) is found almost universally in children with DS. In general, in the first 24 months of life, children pass developmental milestones at twice the age of typically developing children. Mental developmental quotients on the Bayley Scales of Infant Development from 6 to 24 months are in the 50s and 60s, while the motor developmental quotients are in the 40s and 50s. At 10 years of age, average developmental quotients are 39.9 (standard deviation: 9.4) with age-equivalent functioning at 51.2 (plus or minus 12.10) months. In adaptive function at 10 years of age, the total age-equivalent level of functioning is 54.4 months, with strength in socialization and weakness in daily living (communication = 45, daily living = 39.7, socialization = 50, combined = 41). Early developmental outcomes at 12 and 24 months correlate with outcomes at 10.7 years (Marchal et al., 2016).

Children with DS are stereotyped as being amiable and happy. Temperament studies, however, have shown them to have behavioral profiles comparable to typically developing children (Chapman & Husketh, 2000). Compared with the general population, individuals

with DS are at increased risk for experiencing behavioral, emotional, and psychiatric problems (18%–23%). But compared with other children with IDs who are at 30%–40% risk, children with DS are at decreased risk. Children and youth with DS have been found to have high rates of provocative behaviors and low-level aggressive behaviors (e.g., 73% disobedient, 65% argumentative, and 50% demanding attention). In addition, 6%–8% of children with DS are diagnosed with ADHD, like Jerome in our case study (Dykens, 2007). The prevalence of psychotropic medication use in children and adolescents with DS is higher than in the general population (25% versus 17%). Nervous system stimulants are most frequently prescribed for children from 5 to 11 years, with declining use thereafter. By contrast, the use of SSRI for the treatment of anxiety and depression increases into adolescence and young adulthood (Downes, Anixt, Esbensen, Wiley, & Meinzen-Derr, 2015). There are some reports of psychosis or depression with psychotic features in adolescents and young adults, with marked motoric slowing in daily activities and in expressive language (Dykens et al., 2015).

The reported prevalence of autism spectrum disorder (ASD) in DS is between 7% and 16%. (Dykens, 2007; Richards, Jones, Groves, Moss, & Oliver, 2015). In those who have regression with the development of autism, the loss of language is reported to occur later than in non-DS autism development (61.8 months versus 19.7 months; Castillo et al., 2008). In addition, children with DS who have autism have poorer development in all areas, and seizures are more likely.

DS disintegrative disorder is a rare phenomenon of acute or semi-acute cognitive and functional decline that can have features of autism or depression; it generally occurs in the preteen or teen years. Extensive evaluations may identify dysfunctional sleep or thyroid dysfunction. Most are treated with SSRIs, and generally upon follow-up months to years later, 50% are somewhat better (Mircher et al., 2017; Worley et al., 2015).

It appears that virtually all individuals with DS have the characteristic neuropathology of Alzheimer's disease by 45 years of age, although not all individuals have clinical signs. They have increased concentrations of brain amyloid, which is associated with neurofibrillary tangles. A number of genes on chromosome 21 have been implicated in Alzheimer's disease (Lott & Dierssen, 2010).

Intervention: Educational and Services

Parents of a newborn with DS should be provided with a balanced view of the possible outcomes and information on intervention and support. They should be given current materials on infants with DS and contact

information for the point of entry for the early intervention system (see Chapter 31). In addition, information regarding local and national parent support /advocacy programs such as the National Down Syndrome Society (www.ndss.org, which focuses on advocacy), the National Down Syndrome Congress (www.ndscenter.org, which focuses on the needs of families and offers an annual meeting), and Gigi's Playhouse (www.gigisplayhouse.org, which provides an array of programs and support) should be offered. Information on respite care and supplemental security income (SSI) is also helpful (see Chapter 37).

The educational program of the child with DS needs to provide the optimal environment for learning. A balance of inclusion in learning environments with typically developing children and the provision of specialized therapeutic interventions needs to be planned to meet each child's needs (Chapter 33). Most frequently, children with DS have strengths in visual-motor skills, and so a visual approach to teaching that uses aids such as written instructions, visual organizers, and schedules capitalizes on this strength. Data indicate that an inclusive educational setting supports academic development, especially in the areas of language and literacy (de Graaf & van Hove, 2015).

In their role as advocates for their child with DS, most parents consider using alternative and complementary therapies for improvement in cognitive function (Prussing, Sobo, Walker, & Kurtin, 2005). Eighty-seven percent of these parents do at some time treat their child with an alternative therapy, most commonly combination nutritional therapy (e.g., Nutrivene; Ellis et al., 2008; Prussing et al., 2005; Vacca & Valenti, 2015; see Chapter 39). Although there are many studies of alternative therapies in individuals with DS, few meet even the minimal methodology criteria of scientific studies (Roizen, 2005). The efforts to improve the health and lives of individuals with DS have resulted in the development of the Down Syndrome Medical Interest Group, which includes a network of Down syndrome clinics (Box 15.1; www.dsmig-usa.org) and also has resulted in the formation of organizations within the research community (including the National Institutes of Health) with the purpose of developing a data collection site that parents can populate with information on their child (www.dsconnect.nih.gov) as well as the development of the Trisomy 21 Research Society (Delabar et al., 2016).

Outcomes

Since the 1970s, the prognosis for a productive and positive life experience for individuals with DS and their families has continued to improve, with the credit going to the efforts of parents' advocacy. But significant

barriers remain. The most difficult challenges include medical complications, bullying or ostracism, disappointments regarding the achievement of certain adult milestones (e.g., obtaining a driver's license), and a lack of adequate services and supports in adulthood (Hanson, 2003). However, there is increased interest in adults with DS and increased efforts to review the limited data on adults (Steingass, Chicoine, McGuire, & Roizen, 2011) and develop health care guidelines (Capone et al., 2018).

With the introduction in the 1980s of **supported employment** (in which individuals with disabilities have a job coach), adults with DS are able to hold jobs with improved pay, improved benefits, and better working conditions. In a survey about employment completed by parents regarding their adult children with DS, 50% were employed in some capacity, with 3% of those in competitive employment (Kumin & Schoenbrodt, 2015). Most frequently for individuals with special needs like those with DS, employment is in food services, landscaping, filing, factories, and environmental services.

FRAGILE X SYNDROME

Prevalence

FXS is the most common known single-gene cause of ID and ASD, with an estimated frequency of about 1 to 4,000 to 5,000 (Coffee et al., 2009). Prevalence varies somewhat between different populations, but the disorder affects all ethnic groups worldwide.

Genetics

FXS is one of a set of disorders, termed fragile X–associated disorders (FXD), which are caused by mutations of the *FMR1* gene on the X chromosome (see Chapter 1). These mutations involve the expansion of a trinucleotide repeat (CGG) sequence in the promotor region of the *FMR1* gene. The **promotor region** of a gene controls the transcription of that gene into mRNA, which is then translated into a functional protein—in this case, the fragile X mental retardation protein (FMRP). Normally, the promotor region of the *FMR1* gene has 5 to 44 CGG repeats, which allows for normal transcription and translation of the gene. Some individuals have 55 to 200 CGG repeats; they are said to have a **premutation**. The prevalence of premutation is estimated to be about 1 in 151 to 1 in 209 females and 1 in 430 to 1 in 468 males in the United States. The premutation is associated with two well-defined adult-onset diseases: FXTAS (a late-onset progressive neurological disorder) and fragile X–associated primary ovarian insufficiency (FXPOI).

These individuals are still able to produce FMRP, the gene product of the *FMR1* gene, so they *do not* have FXS (although individuals with more than 150 repeats may have some characteristics of FXS due to a mild reduction in FMRP; Willemsen, Levenga, & Oostra, 2011).

For most female premutation carriers, there is an increased risk for passing on the *FMR1* gene as a **full mutation** (more than 200 CGG repeats); male premutation carriers (and, surprisingly, even males with the full mutation) can only pass the premutation to their offspring (Yrigollen et al., 2014). The full mutation results in silencing of the *FMR1* gene so little or no *FMR1* mRNA is made, and thus most males with the full mutation make little or no FMRP. The substantial reduction or lack of FMRP is what causes these individuals to have FXS. Because the *FMR1* gene is located on the X chromosome, girls who receive the full mutation from their mothers will have a normal *FMR1* gene on the X chromosome that they receive from their fathers. They would therefore have at least some production of FMRP and tend to have milder manifestations of the symptoms of FXS (Loesch, Huggins, & Hagerman, 2004). By contrast, boys who receive the full mutation from their mothers receive no counterbalancing normal *FMR1* gene from their fathers and so have the typical features of FXS (with some variability in severity depending on differences in FMRP production and variation in the amount of gene inactivation in different cells in the body [mosaicism]; Willemsen et al., 2011). Because *FMR1* expansions tend to increase in size as they are passed from generation to generation, FXDs affect families in multiple generations.

Physical Features, Typical Presentations, Diagnostic Testing, and Early Identification

Physical features of FXS include macro-orchidism (large testes) in virtually all adult males with FXS. A characteristic pattern of facial features is seen in a percentage of individuals with FXS, including prominent ears, macrocephaly (large head), long face, prominent jaw and forehead, midfacial hypoplasia (reduced dimensions of the midfacial area), and high arched palate. Connective tissue laxity, leading to hyperextensible joints, flat feet, and soft skin, is common in FXS but not present in all individuals (Hagerman & Hagerman, 2002). Physical features are sufficiently variable that they cannot be used as indicators of which individuals to screen for the presence of FXS.

Developmental delays are the first sign of FXS. Motor development is often only mildly delayed; the most common presentation leading to an FXS diagnosis

is speech delay, which is seen in most boys with FXS and a significant proportion of girls. Some higher functioning boys and many girls present at school age with behavioral difficulties, ADHD, anxiety, or academic delay.

The average age of diagnosis of FXS is about 3 years (Bailey, Raspa, Bishop, & Holiday, 2009), although developmental delays can be identified in most boys by age 9–12 months (Box 15.3). There has been a recent collaborative initiative (CDC & AAP, 2016) of the AAP, CDC, and FXS community to bring the age of diagnosis down to 2 years or less, to obtain earlier intervention, and earlier family counseling regarding genetic risks and reproductive options to allow for prenatal testing or preimplantation genetic diagnosis. Pilot newborn screening studies for FXS have been conducted (Bailey et al., 2017) and are ongoing, but additional work is needed for FXS to be considered for mandatory screening.

Medical Complications

Medical problems more prevalent in FXS than in the general population based on recent data from nine FXS clinics in the Fragile X Clinical and Research Consortium (FXCRC; see Box 15.4) include frequent OM (males 55%, females 46%), strabismus (males 17%, females 13%), seizures (males 12%, females 3%, usually in childhood), sleep disorders (males/females 27%), gastroesophageal reflux (males/females 11%), sleep apnea (males/females 7%), and loose stools (males 12%, females 7%) (Kidd et al., 2014; see Figure 15.3). Treatment of medical problems is important as these problems can impact development and behavior. Primary care physicians should look for and ask about symptoms that might be related to these problems at routine yearly well-child visits and should refer to specialists for further evaluation and management if needed. The type and timing of follow up for these problems will depend on severity and whether medication intervention is implemented.

Treatment of Medical Problems

Since children with FXS have expressive language delays and recurrent OM that may lead to conductive

hearing loss and further language and articulation issues, it is important that all OM and any other ear-related issues be treated promptly and appropriately. Hearing should be monitored carefully, and there should be a relatively low threshold for early pressure equalization tube placement in children with FXS and recurrent OM (Bennett & Haggard, 1999). If chronically infected adenoids and tonsils become a problem, adenoidectomy and/or tonsillectomy may be performed at the same time as the PE tubes are inserted.

Children with FXS should have vision screening yearly or every other year during childhood to ensure that any acuity issues are being addressed so these do not compound problems with reading and academics. When present, strabismus should be managed with eye patching, vision therapy, or surgery to avoid amblyopia and aggravation of visual processing problems.

For concerns about episodes that might be seizures, an electroencephalogram (EEG) should be obtained (see Chapter 22). The EEG can be used to distinguish behavioral spells from seizures. Typically, individuals would be treated after two documented seizures with anticonvulsants that are least likely to cause sedation (Berry-Kravis et al., 2010), with a plan to discontinue treatment after an individual with FXS is seizure-free for 2 years.

Monitoring and managing obstructive sleep apnea and other sleep problems are of particular importance in FXS due to their relationship to decrements in daytime performance and behavior (Goodlin-Jones, Tang, & Anders, 2009; Kronk et al., 2010). Sleep problems may require behavioral or medical treatment. When symptoms of obstructive sleep apnea are clearly present, management with tonsillectomy/adenoidectomy is indicated.

Individuals with FXS have increased risk for being overweight and for somewhat diminished height in adulthood. It is important to encourage healthy diet, calorie restriction when necessary, and exercise programs for 30–40 minutes four to five times a week to minimize problems associated with increased weight.

When GE reflux is present, antacids should be used when needed to prevent pain and esophagitis. As individuals with FXS are not always able to describe heartburn, the only sign of GE reflux may be behavioral

BOX 15.3 EVIDENCE-BASED PRACTICE

Testing for Fragile X Syndrome

Diagnostic testing for fragile X syndrome (FXS) is recommended for all children who have intellectual disability or developmental disabilities of undetermined etiology. Children with FXS have developmental delay identified by 9–12 months, but the average age of diagnosis is 3 years. Bailey and colleagues (2017) are conducting a pilot newborn screening study that could enable early identification and targeted intervention.

BOX 15.4 INTERDISCIPLINARY CARE**The Fragile X Clinical and Research Consortium**

The Fragile X Clinical and Research Consortium (FXCRC; <https://fragilex.org/research/>) was created in association with the National Fragile X Foundation in 2006 to establish standards of care for fragile X syndrome (FXS) with optimized care delivery at sites geographically more available to families relative to the prior few clinics specializing in FXS. The FXCRC has grown from 11 to 27 clinics, has published on medical problems, and has created consensus documents regarding the management of issues important for those with FXD. These documents are published on the NFXF web site and are updated at regular intervals (<https://fragilex.org/2017/treatment-and-intervention/consensus-fragile-x-clinical-research-consortium-clinical-practices/>). The majority of clinics that have joined the FXCRC feel that the organization has been helpful for improving clinical care, providing more services, and increasing the ability of the clinic to participate in clinical trials (Liu et al., 2016). It also appears that when individuals are seen at an FXCRC specialty clinic, unmanaged issues are identified and can be treated (Visootsak et al., 2016).

The FXCRC also serves as a research network to allow recruitment of cohorts across multiple sites to better study the FXS population without the biases of small studies. Most of the FXCRC clinics participate in and contribute data to the FORWARD (Fragile X Online Registry with Accessible Research Database) longitudinal natural history study of FXS, which is funded by the CDC (Sherman et al., 2017). This study is expected to produce extensive information about the life trajectory of FXS in terms of medical, educational, functional/adaptive, behavioral, vocational, and social issues.

outbursts occurring in patterns during the day in relation to meals or sleep dysfunction with frequent night awakenings.

Some individuals with FXS benefit from orthotics or shoe inserts for foot pronation and flat feet to help with motor development when young and to avoid leg pain and reduce gait problems when older.

Figure 15.3. Frequency of medical conditions in FXS in the United States relative to control populations of typically developing children. (Sources: Fragile X Clinical and Research Consortium: www.fragilex.org; Kidd et al., 2014). (Key: FXS, fragile X syndrome; GERD, gastroesophageal reflux disease.)

Neurodevelopment, Cognitive Profile, and Behavioral Issues

The majority of males with FXS will meet criteria for mild to severe ID (Kaufmann, Abrams, Chen, & Reiss, 1999). Average IQ in adult males with FXS is 40–50, with a mental age of about of 5–6 years. Females with FXS are often less affected than males, with about 25% having cognitive impairment and others frequently being diagnosed with learning disabilities (de Vries et al., 1996). Average IQ in females is about 80, with a range from severe impairment to normal or even superior ability. There is a relatively consistent pattern of intellectual weaknesses and strengths distinct to both males and females with FXS, generally milder in severity in females (Freund, Reiss, & Abrams, 1993). Relative weaknesses include visuospatial skills, working memory, processing of sequential information, and attention (Dykens, Hodapp, & Leckman, 1987) while there are relative strengths in visual memory, simultaneous processing, and long-term memory (see Chapters 13 and 20). These patterns are important to recognize to optimize education programming.

The full-scale IQ score decreases with age as children with FXS become older (Dykens et al., 1987; Fisch et al., 1996; Fisch et al., 1999). Standard scores on the Vineland Adaptive Behavior Scale for overall adaptive behavior as well as subdomains decline with age

during childhood, in males more so than in females with FXS (Klaiman et al., 2014). Decline in standard scores for intelligence and adaptive function does not reflect regression but rather failure to keep pace with the normal rate of intellectual development. These scores are stable in adulthood.

The behavioral phenotype in males with FXS covers a wide spectrum. Most common broad categories of behavioral dysfunction seen in FXS are attention/hyperactivity, hyperarousal, anxiety, and aggression. Females with FXS have the same spectrum of behavioral difficulties but with milder symptomology.

Attention disorders, including impulsivity, hyperactivity, and inattention, are extremely common in FXS and result in a comorbid ADHD diagnosis in as many as 73% of males (Baumgardner, Reiss, Freund, & Abrams, 1995; Hagerman & Falkenstein, 1987; Turk, 1998) and 30%–63% of females (Freund et al., 1993; Hagerman et al., 1992; Mazzocco, Pennington, & Hagerman, 1993). Anxiety disorders, including generalized anxiety and particularly specific phobias and social anxiety (Cordeiro, Ballinger, Haberman, & Hessler, 2011; Freund et al., 1993; Hagerman et al., 1992), have been reported in 86.2% of males with FXS and 76.9% of females with FXS (Cordeiro et al., 2011).

Hyperarousal, an overreaction to sensory input, can be triggered in FXS by a wide range of situations, including noises, new environments, crowds, interpersonal distance, eye contact, and new people (Cohen, 1995). The effects of this hyperarousal are widespread and include high levels of motor activity (e.g., running and jumping), stereotypic motor movements (e.g., hand flapping), gaze aversion, and perseverative behaviors (Bailey et al., 1998; Belser & Subhalter, 2001; Cohen, 1995).

Aggression and self-injurious behavior (SIB) are often linked to hyperarousal or anxiety and are especially detrimental to family functioning, quality of life (Bailey et al., 2012), and participation in daily activities. SIB typically begins at 1 to 3 years of age (Symons, Byiers, Raspa, Bishop, & Bailey, 2010). Aggression typically occurs later, frequently during the pubescent and postpubescent periods (Bailey et al., 2012).

Language development is significantly delayed for most individuals with FXS. In general, individuals with FXS have stronger receptive than expressive language skills (McDuffie, Kover, Abbeduto, Lewis, & Brown, 2012), with particular strengths in receptive vocabulary. Pragmatic language (see Chapter 17) is also delayed, and young children with FXS have been shown to have difficulties with joint attention, reciprocating positive facial expressions, eye gaze, and turn-taking (Murphy & Abbeduto, 2005; Roberts, Mirrett, Anderson, Burchinal, & Neebe, 2002). Males with FXS

demonstrate high rates of perseverative language, tangential (off-topic) language, overly literal interpretation of language, and decreased topic initiation and maintenance (Bailey et al., 1998; Sudhalter, Cohen, Silverman, & Wolf-Schein, 1994).

About one half to two thirds of males and about 20% of females with FXS meet the criteria for ASD (Wang, Berry-Kravis, & Hagerman, 2010; see Chapter 18). These two disorders share multiple behaviors, including pragmatic deficits, language delays, reduced eye contact, difficulty with regulation of attention and activity level, SIB, and aggression. Characteristics that tend to differ between FXS and idiopathic ASD include a higher rate of ID, more severe motor coordination deficits, worse expressive than receptive language, generally higher interest in socialization (although limited by anxiety), and better imitation skills in FXS relative to idiopathic ASD. Children with FXS and a codiagnosis of ASD are at higher risk of seizures and chronic sleep disorders, more severe behavioral issues in all areas except anxiety, and higher use of antipsychotics and alpha-agonists to target aggressive behavior relative to those with FXS without ASD (Kaufmann et al., 2017).

Supportive Interventions for Educational and Behavioral Problems

Current treatment of FXS includes therapy, educational strategies that take into account cognitive and behavioral strengths and weaknesses in FXS, treatment of medical problems, behavioral modification, and psychopharmacology for behaviors creating dysfunction (Berry-Kravis, Sumis, Hervey, & Mathur, 2012).

Occupational therapy, physical therapy, and speech therapy should be included as part of a comprehensive intervention program based on the specific needs of the individual child with FXS. Therapy techniques that have been validated for autism are often helpful for FXS, but they must be modified based on what is known about the FXS phenotype. Individuals with FXS have been shown to display better behavioral and adaptive functioning when their environment and supportive programming are well matched to their needs (Hessler et al., 2001), and therefore a highly individualized behavioral, therapeutic, and educational intervention plan is needed both for home and school or work environments.

The use of medications such as stimulants for attention and hyperactivity, SSRIs for anxiety, alpha-agonists for hyperactivity and overarousal, and antipsychotics for irritable and aggressive behaviors appears to be helpful by assessment in a clinical setting in approximately 50%–70% of patients (Berry-Kravis

et al., 2012; see Chapter 27). Response is not complete, however, and data from a national survey on FXS showed that approximately 10%–20% of respondents thought that medication was not helpful at all for behavior problems, while only approximately 40% felt the medication was helping a lot (Bailey et al., 2012). Thus, there is a clear unmet need in FXS for better treatments for behavior and for any treatments that target cognitive deficits. Treatments that modify the underlying disorder would be an extremely important advance (see Box 15.4 for more information on FXCRC).

Progress Toward Targeted Treatment

Recent studies of the neurobiology and synaptic mechanisms resulting from absence of the FMRP in FXS have become an important window on future targeted treatments for FXS, ASD, and related neurodevelopmental disorders (Wang et al., 2010; Yu & Berry-Kravis, 2014). FMRP is an mRNA binding protein that regulates the expression of proteins at synapses in neurons and thus is involved in adjusting synaptic strength and plasticity in response to activation of a particular neuron (Berry-Kravis, 2014; Huber, Gallagher, Warren, & Bear, 2002). An animal model of FXS, known as the *Fmr1* knockout mouse, makes no functional FMRP. It has been a critical resource in understanding the role of FMRP in neurons, identifying cellular targets for treatment, and exploring the effects of potential disease-modifying agents. Successful preclinical testing of disease-targeted treatments in mice, rats, and flies has demonstrated reversal of disease phenotypes (particular features of neurons and behaviors seen in the FXS animal models), leading to a number of early-phase and several larger clinical trials in humans (Berry-Kravis et al., 2016; Berry-Kravis et al., 2017; Gross, Hoffman, Bassell, & Berry-Kravis, 2015; Youssef et al., 2018). These studies have been plagued by uncertainties about how to optimally demonstrate treatment effects and disease modification in a clinical trial setting for a population of individuals with developmental disabilities (Berry-Kravis et al., 2016; Berry-Kravis et al., 2017; Erickson et al., 2017; Gross et al., 2015; Youssef et al., 2018). Major trial design issues include variable dosing windows; the timing (age) and length of treatment necessary; the need for cognitive/behavioral interventions to assess drug effects on learning; large placebo effects; and the lack of validated, sensitive biomarkers and functional outcome measures in FXS (Berry-Kravis et al., 2013; Budimirovic et al., 2017; Erickson et al., 2017). Work is ongoing to resolve these issues so that in the future, treatment to reverse the underlying disorder will eventually replace or complement supportive treatment.

There is significant overlap in molecular and cellular pathways involving FMRP, and FMRP binds to and regulates many key autism gene products (Iossifov et al., 2012; Steinberg & Webber, 2013; Waltes et al., 2014). Thus, progress in development of targeted treatments for FXS may result in targeted treatments to reverse CNS defects and clinical manifestations of ASD, other neurodevelopmental disabilities, and ID.

SUMMARY

- DS is associated with a variety of medical conditions and complications in nearly all organ systems.
- There is a risk for **diagnostic overshadowing**, which can lead to postponing or missing a diagnosis. Therefore, it is important for health care providers to closely evaluate individuals with DS for medical concerns and be vigilant with their medical care.
- An appropriate educational program for a child with DS should provide a balance of inclusion in learning environments with typical children and therapeutic interventions for each child's needs.
- Treatment of medical problems in both DS and FXS is important as they can impact development and behavior.
- Early identification of FXS enables early intervention.
- FXCRC is seeking to develop targeted treatments of FXS to improve development and behavior.

CHAPTER 16

Inborn Errors of Metabolism

Nicholas Ah Mew, Erin MacLeod,
and Mark L. Batshaw

Upon completion of this chapter, the reader will

- Understand the term *inborn error of metabolism*
- Know the differences among a number of these inborn errors, including amino acid disorders, organic acidemias, fatty acid oxidation defects, mitochondrial disorders, peroxisomal disorders, and lysosomal storage diseases
- Identify the characteristic clinical symptoms and diagnostic tests for these disorders
- Know which of these disorders have newborn screening tests available
- Recognize different approaches to treatment
- Understand the outcome and range of developmental disabilities associated with inborn errors of metabolism

The food we eat contains fats, proteins, and carbohydrates that must be broken down into smaller components and then metabolized by thousands of enzymes that maintain body functions. Approximately 1 in 2,500 children are born with a deficiency in one of the enzymes that normally catalyzes an important biochemical reaction in the cells (OMIM, 2018). These children are said to have an inborn error of metabolism. Such an enzyme deficiency can result in the accumulation of a toxic chemical compound behind the enzyme block or lead to a deficiency of a product normally produced by the deficient enzyme (Figure 16.1). The result may be organ damage or dysfunction (often the brain), varying degrees of disability, or even death. For example, children with phenylketonuria (PKU) have a deficiency in the enzyme that normally converts one amino

acid (phenylalanine) to another (tyrosine). An inherited deficiency of this enzyme (phenylalanine hydroxylase) leads to the accumulation of phenylalanine, which at high levels is toxic to the brain (Figure 16.1; Jahja et al., 2017; Singh et al., 2014; Vockley et al., 2014). If PKU is not recognized and treated soon after birth, severe intellectual disability ensues. In contrast, in children with congenital adrenal hypoplasia, an inherited enzyme deficiency leads to decreased production of certain steroid hormones (e.g., cortisol) that are essential for typical body function. Females with this deficiency may be born with ambiguous genitalia because they produce abnormal amounts of the male steroid sex hormone (testosterone) *in utero* (Auchus, 2015; Turcu & Auchus, 2015). Fortunately, for these disorders and others, newborn screening tests and early treatment have

Figure 16.1. Inborn errors of metabolism are genetic disorders involving an enzyme deficiency. This enzyme block leads to the accumulation of a toxic substrate and/or the deficient synthesis of a product needed for normal body function. In PKU, there is a toxic accumulation of phenylalanine behind the deficient enzyme, phenylalanine hydroxylase.

permitted children who are affected to grow up with typical intelligence and normal physiological functioning. Not all inborn errors of metabolism can be as effectively treated, however, because of delays in diagnosis or lack of an effective intervention. This chapter provides examples from a range of inborn errors of metabolism to explain diagnostic and therapeutic advances that are improving the outcome of people with these disorders.

■ ■ ■ CASE STUDY

Lisa was discharged from the hospital at 3 days of age. Her parents were surprised and upset when they were called back a week later after doctors reported that she had abnormal results for her screening test for PKU. Amino acid studies confirmed the diagnosis of PKU, and Lisa was placed on a formula that was free of phenylalanine. She was also allowed to breastfeed a small amount. As Lisa grew, her parents could hardly believe there was a problem because Lisa looked and acted like a typically developing child and achieved her developmental milestones on time, sometimes making PKU seem like a “silent disorder.” The visits to the metabolism clinic were focused on educating her parents and Lisa about her special diet. Though Lisa struggled to find independence, her providers would remind her of the importance of “diet for life.” As a result of dietary indiscretions, Lisa had poor metabolic control that began to impact her academic performance. She was unfortunately found to be a nonresponder to the pharmaceutical interventions available, requiring her to continue her strict dietary regimen. She eventually graduated from college, got married, and recognized the importance of returning to her special diet in order to have a healthy infant and avoid the manifestations of uncontrolled maternal PKU, which include microcephaly, intellectual disability, and heart defects in her baby.

■ ■ ■ CASE STUDY

Darnel babbled at 6 months and sat without support shortly thereafter. His parents became concerned, however, when at 1 year of age he had made no further progress. If anything, he seemed less steady in sitting and was uninvolved with his surroundings. His pediatrician worried that Darnel might have an autism spectrum disorder. By 18 months, there were graver concerns. Darnel was no longer able to roll over; he was very floppy and did not appear to respond to light or sound. His pediatrician referred Darnel to a genetics clinic, where an extensive workup eventually diagnosed him as having Tay-Sachs disease, a genetic disorder affecting lipid metabolism in the brain. Over the next 3 years, Darnel slipped into an unresponsive condition and required tube feeding. He finally succumbed to aspiration pneumonia. As a result of the diagnosis, his parents decided to undergo prenatal diagnosis in subsequent pregnancies. They now have two healthy children, and his mother underwent one termination of a fetus that was affected.

Thought Questions:

As a metaphor for inborn errors of metabolism, imagine that the human body is an efficiently run city and that each road represents a chemical reaction catalyzed by a unique enzyme. What happens to car traffic in the city if one of the roads is blocked? How would this differ if it were a major highway that was blocked versus a small road? How about if only two lanes of the highway were obstructed rather than the whole highway? What if the only road to the only electric power plant is permanently blocked? What would happen to the parking lot of the car manufacturing plant if its exit were obstructed?

TYPES OF INBORN ERRORS OF METABOLISM

Inborn errors of metabolism were first described approximately 100 years ago (Garrod, 1908). Since then, a number of new metabolic disorders have been described each year. In fact, over 300 additional disorders have been identified in the last decade alone (Saudubray et al., 2016). The majority of these enzyme deficiencies are inherited as autosomal recessive traits, in which both parents carry a genetic change on one of their two copies of the gene (see Chapter 1). These carriers are healthy and develop typically due to the normal second copy of the gene. Individuals who are affected usually inherit two abnormal genes and have no normal version. A few metabolic disorders are transmitted as X-linked disorders or through mitochondrial inheritance (see Chapter 1). Prenatal diagnosis is available for

most of these disorders (see Chapter 4). See Table 16.1 for further classifications of metabolic disorders.

Although there are many different ways of categorizing these disorders, inborn errors of metabolism are often divided into 1) those that are clinically “silent” for a relatively long period before being recognized, 2) those that produce acute metabolic crises, and 3) those that cause progressive organ damage or dysfunction (Table 16.2).

Among the silent disorders are certain abnormalities involving amino acids or organic acids (e.g., PKU) or metals (e.g., Wilson disease). Disorders producing acute toxicity include certain inborn errors in the metabolism of small molecules, including ammonia, amino acids, organic acids, fatty acids, lactic acid, and simple sugars (Levy, 2009a, 2009b; Vernon, 2015). Inborn errors of metabolism causing progressive disorders include most **glycogen** storage and peroxisomal and lysosomal storage disorders. The specific names of the disorders are often derived from their deficient enzyme (e.g., **ornithine transcarbamylase [OTC] deficiency**, a urea cycle disorder [UCD]).

Silent disorders, such as PKU, do not manifest as life-threatening crises, but if left untreated, they lead to irreversible brain damage and developmental disabilities. These disorders contrast with inborn errors that cause episodic symptoms, such as OTC deficiency, that may be acutely life-threatening with each decompensation, typically starting in early infancy. In both cases,

an infant who is affected is generally protected in the womb because the maternal circulation can remove the toxic chemical or provide the missing product. After birth, however, the infant must rely on his or her own metabolic pathways, and if they are abnormal, toxicity occurs rapidly or over time, depending on the severity of the defect. In progressive disorders, there is a gradual accumulation of large molecules. These molecules are stored in the cells of various body organs, including the brain, where they ultimately cause damage, leading to physical or neurological deterioration. Many of the small-molecular disorders, both those that are silent and those with acute symptoms, are treatable with fairly good outcome if treatment is started early. The large-molecular disorders, with a few notable exceptions, have been far more difficult to treat, and their outcome generally remains poor.

Clinical Manifestations

The clinical manifestations of the various inborn errors of metabolism fall along a spectrum, from lack of overt symptoms to life-threatening episodes.

The silent disorders like PKU do not manifest symptoms such as lethargy, coma, or regression of skills. Instead, children who are untreated develop at a slower-than-expected rate and are usually not identified as having intellectual disability until later in childhood.

Table 16.1. Categorical classification of metabolic disorders*

Protein-related metabolic disorders	Proteins are large molecules (macromolecules) composed of chains of amino acids (AAs) Proteins are the main structural components of the cells and tissues of the body Special proteins called enzymes catalyze (speed up or facilitate) chemical reactions in the body Protein in food (a macronutrient) is present in meat, fish, dairy, and eggs in large amounts, and in plants (especially beans and legumes) in smaller amounts	
Disorder	Metabolic defect	Examples
Aminoacidopathies	Proteins are broken down into AAs Defects in the early steps of the breakdown of AAs lead to accumulation of specific AAs that are toxic in high amounts Abnormal quantities of AAs are found in the blood (abnormal quantitative plasma AAs)	<i>Phenylketonuria</i> (excess AA phenylalanine)** <i>Maple syrup urine disease</i> (excess branched-chain AAs: leucine, isoleucine, valine) <i>Homocystinuria</i> (excess AA homocysteine and methionine) <i>Tyrosinemia</i> (excess AA tyrosine)
Organic acidemias	AAs are broken down into organic acids (OA) and ammonia (NH ₃) Defects in later steps in the breakdown of AAs lead to an accumulation of OAs, NH ₃ , and other metabolic by-products (e.g., acyl carnitine) in the blood OAs acidify the blood, causing metabolic acidosis OAs and other metabolic byproducts accumulate in the urine (abnormal quantitative urine OAs)	<i>Propionic acidemia</i> <i>Methylmalonic acidemia</i> <i>Glutaric acidemia type I</i> <i>Isovaleric acidemia</i>

(continued)

Table 16.1. (continued)

Urea cycle disorders	AAs are broken down into OA and NH₃ Ammonia is toxic and must be converted into urea and excreted by the kidneys Defects in the synthesis of urea from ammonia result in accumulation of ammonia in the blood (hyperammonemia), abnormalities of plasma AAs, and the presence of orotic acid in the urine	<i>Ornithine transcarbamylase deficiency</i> Citrullinemia Arginosuccinic aciduria
Fat-related metabolic disorders	Fats are large molecules (macromolecules) composed of long fatty acid (FA) chains held together by a small molecule (glycerol) Fats are the main energy storage molecules of the cells and tissues of the body Fats in food (a macronutrient) are present in meat, fish, dairy, and eggs as animal fats and in plants as oils	
Disorder	Metabolic defect	Examples
Fatty acid oxidation disorders	Fats are broken down into FAs Defects in the breakdown of FAs lead to accumulation of FA byproducts called acyl carnitines (abnormal acyl carnitine profile) Defects in the breakdown of FAs lead to decreased production of glucose, resulting in low blood sugar, especially after fasting (hypoglycemia)	Medium-chain acyl CoA dehydrogenase deficiency Long-chain 3-hydroxy acyl CoA dehydrogenase deficiency Very long-chain acyl CoA dehydrogenase deficiency Primary carnitine deficiency
Carbohydrate-related metabolic disorders	Carbohydrates are large molecules (macromolecules) composed of chains of simple sugars Carbohydrates are a major energy source for the body and are stored as glycogen in the liver and in muscles Carbohydrates in food (a macronutrient) are present in fruits, vegetables, and grains; the sugar lactose is present in milk, and other sugars, such as fructose, are present in fruit	
Disorder	Metabolic defect	Examples
Disorders of carbohydrate/sugar metabolism	Carbohydrates are broken down into sugars Defects in the breakdown of sugars leads to an accumulation of toxic amounts of the sugar and metabolic products in the body (abnormal plasma sugar levels) Untreated infants develop jaundice, liver dysfunction, blood clotting abnormalities, and severe infections	<i>Galactosemia</i> Hereditary fructose intolerance
Disorders of carbohydrate degradation	Carbohydrates are stored in the liver and in muscles as the macromolecule glycogen The liver utilizes glycogen to later provide a slow release of glucose to the rest of the body and maintain blood glucose levels In contrast, each muscle (including the heart) stores carbohydrates as glycogen for its own future use Defects in the breakdown of glycogen result in accumulation of toxic quantities of glycogen in the liver or muscles or both A defect in liver glycogen breakdown may result in hypoglycemia and liver failure A defect in muscle glycogen breakdown may result in muscle pain, fatigue, and heart failure (cardiomyopathy) One disorder of carbohydrate degradation (Pompe disease) is also classified as a lysosomal disorder because the deficient enzyme is located in lysosomes	Hepatic <i>glycogen storage diseases</i> (e.g., type I, III, IV, VI) Muscle <i>glycogen storage diseases</i> (e.g., type II, V)
Lysosomal disorders	Lysosomes are spherical organelles found in the cytoplasm of cells throughout the body Lysosomes contain enzymes that “digest” large, complex molecules (macromolecules) including mucopolysaccharides (made of complex chains of sugars, also known as glycosaminoglycans [GAGs]) and sphingolipids (specially modified lipid molecules)	

Disorder	Metabolic defect	Examples
Mucopolysaccharidoses (MPSs)	Lysosomes are deficient in enzymes that break down MPSs/ GAGs MPS molecules accumulate in tissues Urine GAG analysis is used as a screening test for MPSs	<i>MPS I (Hurler syndrome)</i> <i>MPS II (Hunter syndrome)</i> <i>MPS III (Sanfilippo syndrome)</i> <i>MPS IVa (Morquio syndrome)</i> <i>MPS VI (Maroteaux-Lamy syndrome)</i> <i>MPS VII (Sly syndrome)</i>
Sphingolipidoses	Lysosomes are deficient in enzymes that break down sphingolipids Sphingolipids are present to varying degrees in different tissues of the body, many of which are important in the nervous system Types of sphingolipids include sphingomyelin, globosides, and gangliosides	<i>Tay-Sachs disease</i> <i>Niemann-Pick disease type A and B</i> <i>Fabry disease</i> <i>Krabbe disease</i> <i>Metachromatic leukodystrophy</i> <i>Gaucher disease</i>
Other lysosomal disorders	Other lysosomal disorders include oligosacchridoses, lipido- ses, and lysosomal transport diseases	Neuronal ceroid lipofuscinoses Sialuria (Salla disease)
Peroxisomal disorders	Peroxisomes are organelles found in the cytoplasm of cells throughout the body Peroxisomes are important in the breakdown (oxidation) of very long-chain FAs (VLCFAs) and branched-chain FAs	
Disorder	Metabolic defect	Examples
Deficiency of peroxi- somal oxidation	Peroxisomes are unable to breakdown VLCFAs or branched- chain FAs Individuals present with neurologic deterioration and devel- opmental regression during childhood	X-linked <i>adrenoleukodystrophy</i>
Severe depletion or absence of peroxisomes (peroxisomal bio- genesis disorders)	Peroxisomes are deficient or absent Infants are born with multiple physical anomalies and neuro- logic and sensory deficits Usually fatal in infancy	<i>Zellweger syndrome</i>
Mitochondrial disorders	Mitochondria are complex, double-membraned organelles found in the cytoplasm of cells throughout the body Mitochondria are critical to the production of energy from the breakdown products of proteins, carbohydrates, and fats Mitochondria are inherited exclusively from the mother and have their own DNA, but most mitochondrial functions rely on the products of nuclear ("regular") genes that are inherited from both parents (see Chapter 1)	
Disorder	Metabolic defect	Examples
Mutations of mito- chondrial DNA	Mitochondria are critical to energy production through the body but are especially important in tissues that have high energy demands The brain, muscles, heart, and eyes are especially affected by mitochondrial dysfunction Individuals affected have a wide range of symptoms, includ- ing stroke-like episodes, diabetes, hearing loss, heart and visual abnormalities, and accumulation of lactic acid in the blood (lactic acidosis)	<i>MELAS (mitochondrial encephalomyopathy, lactic acid, and stroke-like episodes)</i> Kearns-Sayre syndrome
Mutations of nuclear DNA affecting mito- chondrial function	Multiple energy-dependent tissues and organs are affected Affected individuals can present in infancy with severe developmental delays, seizures, muscle weakness, and lactic acidosis and liver dysfunction	Leigh syndrome Mitochondrial depletion syndromes

**Examples of metabolic disorders discussed in the main chapter text are *italicized*. See Appendix B for descriptions of the individual disorders.

Table 16.2. Examples of inborn errors of metabolism

Type I: Silent disorders
Phenylketonuria (PKU)
Type II: Disorders presenting in acute metabolic crisis
Urea cycle disorders (ornithine transcarbamylase [OTC] deficiency)
Organic acidemias (propionic acidemia)
Fatty acid oxidation disorders (very long-chain Acyl-CoA dehydrogenase [VLCAD] deficiency)
Type III: Disorders with progressive neurological deterioration
Lysosomal storage disorders (Gaucher disease, Pompe disease, Fabry disease, mucopolysaccharidoses, Tay-Sachs disease, metachromatic leukodystrophy)
Peroxisomal storage disorders (X-linked adrenoleukodystrophy, Zellweger disease)
Mitochondrial disorders (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes [MELAS])

Life-threatening crises characterize the second group of inborn errors of metabolism. Affected individuals with these disorders appear to be unaffected at birth. Severely affected infants will present by a few days of age with vomiting, respiratory distress, and lethargy before slipping into coma. These symptoms, however, mimic those observed in other severe newborn illnesses such as sepsis (blood-borne infection), brain hemorrhage, heart and lung malformations, and gastrointestinal obstruction, so that making the correct diagnosis is difficult. If specific metabolic testing of the blood and urine is not performed, the disease will go undetected. Undiagnosed and untreated, virtually all children who are affected will die quickly. One study reported that 60% of children with newborn onset inborn errors of the **urea** cycle (causing elevated ammonia level) had at least one sibling who died before the disorder was correctly diagnosed in a subsequent child (Batshaw et al., 1982). Even with “heroic” treatment, which may include **dialysis** to “wash out” the toxin (ammonia), many infants do not survive, and severe developmental disabilities may occur in those who do (Bilgin, Unal, Gunduz, Uncu, & Tiryaki, 2014; Posset et al., 2016).

In children with neonatal-onset disease, DNA analysis typically shows mutations that cause the absence of the enzyme or the formation of a completely nonfunctional enzyme. Enzyme activity levels are generally undetectable (see Chapter 1). By contrast, some children with the same inborn error of metabolism have less severe mutations that result in reduced (rather than absent) amount of enzymes or that result in enzymes that are only partially dysfunctional. These children typically have later onset of clinical signs and more variable or subtle symptoms. For instance, some individuals with fatty acid oxidation disorders do not present in infancy but instead present when illness or exercise results in severe muscle weakness and

breakdown of muscle tissue (Hisahara et al., 2015). In the case of children with milder urea cycle disorders, symptoms of behavioral change, cyclical vomiting, and lethargy are often provoked by excessive protein intake or intercurrent infections such as a gastrointestinal virus or a cold (Lichter-Konecki et al., 2016; Posset et al., 2016). Although these children generally have a better outcome than those with neonatal-onset disease, they remain at risk for life-threatening metabolic crises throughout life. In addition, although their developmental disabilities may be less severe than those in children with neonatal-onset disease, children with later onset disease rarely escape without some residual cognitive impairment, ranging from attention-deficit/hyperactivity disorder (ADHD) and learning disabilities to intellectual disability.

The third clinical presentation of inborn errors of metabolism is in the form of slowly progressive disorders. These often result from the accumulation of a large molecule in a cellular compartment, such as the lysosome or the peroxisome, eventually interfering with cellular processes. Over 50 lysosomal storage disorders (Beck, 2018; Rastall & Amalfitano, 2017) and over 15 peroxisomal disorders (Braverman, D’Agostino, & MacLean, 2013; Wanders et al., 2017) have been described to date.

In the most severe of these disorders, the deleterious effects may begin prenatally, resulting in clinical features at birth that worsen with age. Such is the case with Zellweger syndrome, which may already present at birth with hypotonia, seizures, liver failure, and renal cysts. In other disorders, infants appear unaffected at birth, but they gradually develop progressive loss of motor and cognitive skills beginning in later infancy or early childhood that, if left untreated, commonly leads to death in childhood. In the case of Tay-Sachs disease, Darnel’s disorder in the case study, the child who is affected appears to develop typically

until 3–12 months of age, at which point skill development halts. For the next 1–2 years, the child gradually loses all skills, begins having seizures, and exhibits decreases in muscle tone, vision, hearing, and cognition. Death usually results from malnutrition or aspiration pneumonia. Unfortunately, no effective treatment currently exists for this disorder.

Enzyme replacement therapy, however, has been successful in treating several lysosomal disorders (Gaucher disease, Fabry disease, Pompe disease, and mucopolysaccharidoses) in which target organs other than the brain are accessible to a recombinant (genetically engineered) enzyme (Dornelles et al., 2017; El Dib et al., 2017; Kishnani & Beckemeyer, 2014; Stirnemann et al., 2017). However, the synthetic enzyme does not cross the blood–brain barrier (the network of blood vessels and cells around the brain that acts as a filter for blood flowing to the central nervous system), and so it does not halt or reverse the cognitive effects of these disorders. Some clinical studies have explored injecting synthetic enzyme intrathecally (into the spinal canal so that it reaches the cerebrospinal fluid) as a treatment for disorders in which the brain is a target organ. Medications that reduce production of the toxic metabolite (i.e., substrate reduction therapies) have also been a successful therapeutic avenue and have been used in conjunction with enzyme replacement therapies (Stirnemann et al., 2017). Stem cell and bone marrow transplantation have also been somewhat effective in certain mucopolysaccharidoses and leukodystrophies (Boelens & van Hasselt, 2016; Chiesa, Wynn, & Veys, 2016).

MECHANISM OF BRAIN DAMAGE

The causes of brain damage in the various inborn errors of metabolism are not completely understood. Research is starting to provide some clues that may eventually lead to improved treatment.

Neurotoxins appear to play a role in certain metabolic disorders. For example, in nonketotic hyperglycinemia, an inborn error of amino acid metabolism, there is an accumulation of **glycine**, leading to uncontrolled seizures (Van Hove, Coughlin, & Scharer, 2013). Glycine appears to produce excitotoxicity at a neurotransmitter receptor, leading to the influx of calcium ions and water into the neuron. This causes swelling and, eventually, cell death.

In some disorders, more than one neurotoxin may be involved. Scientists believe that in inborn errors of the urea cycle, the accumulating toxins, both ammonia and glutamine, directly cause nerve cells to swell and indirectly cause excitotoxic damage to the brain (Braissant et al., 2013). If children are rescued from the

ammonia-induced coma within a day or two, the neurotoxic effect can subside and outcome can be fairly good (Bilgin et al., 2014). If the coma is prolonged, however, irreversible brain damage occurs.

ASSOCIATED DISABILITIES

The toxic accumulation of metabolic compounds or the deficient synthesis of essential products results in a range of developmental disabilities in children with inborn errors of metabolism. The most common are intellectual disability and cerebral palsy. However, in certain inborn errors, there are also rather specific impairments. These are sometimes associated with distinctive pathological features in the brain, which may eventually permit a better understanding of brain development and function. For example, children with glutaric acidemia type I, other organic acidemias, and mitochondrial disorders can have dyskinetic cerebral palsy associated with calcifications of the basal ganglia (deep-brain structures important in the control of movement; Falk, 2010; Gitiaux et al., 2008; Gouider-Khouja, Kraoua, Benrhouma, Fraj, & Rouissi, 2010). In Zellweger syndrome, a disorder of **peroxisome** formation, children exhibit multiple malformations that are more commonly associated with chromosomal abnormalities, including an atypical facial appearance, kidney cysts, and congenital heart defects (Braverman et al., 2013). This indicates an embryonic origin of the abnormalities, unlike the other disorders described above, where abnormalities occur as a result of an accumulation of a toxin or lack of a needed product after birth. Prior to birth, the placenta typically acts like a dialyzing system to remove these toxins produced by the fetus.

DIAGNOSTIC TESTING

A genetics evaluation should be considered for all children with significant intellectual or physical disabilities of unknown origin. As a part of that evaluation, particular attention will be paid to potential metabolic disorders if a child displays any of the following signs or symptoms: cyclical behavioral changes, vomiting and lethargy, enlargement of the liver or spleen, cardiomyopathy, evidence of neurological deterioration or regression, or a family history suggestive of an inherited disorder (Kamboj, 2008). An increasing number of clinically available biochemical and molecular tests can lead to a specific diagnosis. In some disorders, early diagnosis leads to therapy with an improved outcome. Even in currently untreatable disorders, a specific diagnosis may permit effective genetic counseling.

A metabolic evaluation is not required, however, for all children with developmental disabilities. It is expensive, and the diagnostic yield is quite low.

Diagnosis of an inborn error of amino acid or organic acid metabolism relies primarily on blood and urine tests to detect toxins or specific biochemical markers. The most common blood tests are for blood ammonia, lactic acid, acylcarnitines, and amino acids; urine is principally tested for organic acids. Metabolic evaluations are individualized based on the specific biochemical pathway that is suspected to be involved. Brain degenerative conditions such as lysosomal storage disorders are typically diagnosed by measuring the suspected deficient enzyme activity in blood or cultured skin cells (Martins et al., 2009). Mutation analysis is increasingly being utilized as a first-line test, as the simultaneous DNA sequencing of numerous suspected genes may more rapidly lead to the diagnosis. Imaging studies (e.g., magnetic resonance imaging, magnetic resonance spectroscopy, computed tomography scan, and electroencephalogram), and other neurological measures (e.g., nerve conduction velocity and electromyography) may also prove helpful in diagnosing these disorders. In many disorders, alterations in brain structure or function are evident on imaging prior to the onset of clinical symptoms.

NEWBORN SCREENING

Because individual inborn errors of metabolism are rare (typically occurring in fewer than 1 in 10,000 births) and the diagnosis is easily missed, efforts have been directed at developing newborn mass screening methods for the detection of the more common and treatable disorders (Weismiller, 2017). In these disorders, rapid diagnosis and treatment are often essential in achieving a favorable outcome; therefore, screening efforts have focused on newborn infants. The first newborn screening test for PKU was developed in 1959, and it was successful in detecting more than 90% of infants who were affected. Subsequently, methods have been established for screening over 30 inborn errors of metabolism as well as other disorders (see Newborn Screening, Chapter 4). This expanded screening, now employing tandem mass spectrometry and other techniques in state-run screening laboratories, is offered to families in newborn nurseries. In the United States, the specific inborn errors of metabolism screened varies between states based on local legislation, which is typically guided by conditions on the recommended uniform screening panel (see Chapter 4). State-specific information is provided by the Health Resources and

Services Administration of the U.S. Department of Health and Human Services (www.babysfirsttest.org).

Although these tests have proved to be remarkably effective, parents should be reminded that a positive test only indicates a higher than normal likelihood of a genetic disorder that needs to be confirmed or ruled out by additional confirmatory testing in the specialized clinic. In addition, the tests detect only a fraction of inborn errors of metabolism, whereas parents might incorrectly assume that these tests are diagnostic for all disorders causing severe developmental disabilities.

THERAPEUTIC APPROACHES

Figure 16.2 illustrates the varying approaches to treating inborn errors of metabolism. These methods include 1) substrate deprivation (limiting the influx of a potentially toxic compound normally metabolized by the defective enzyme); 2) externally supplying the deficient product; 3) stimulating an alternative pathway around the enzyme block; 4) providing a cofactor to stimulate the deficient enzyme; and 5) boosting or restoring enzyme activity by supplying the deficient enzyme, transplanting an organ that has normal enzyme activity, or using gene therapy to correct the genetic defect or to insert a normal copy of the gene. Each of these approaches is illustrated by specific disorders in Table 16.3.

Substrate Deprivation

Most inborn errors of metabolism involve a failure to metabolize to completion one of the three primary macronutrients: carbohydrates, fats, or amino acids. As a result, there occurs a toxic accumulation of an intermediate of the deficient metabolic pathway. Therefore, the mainstay of treatment is dietary restriction of the precursor (carbohydrate, fat, or amino acid) to the potential toxin. For example, children with PKU are placed on a phenylalanine-restricted diet in order to prevent the phenylalanine accumulation that is associated with brain damage (Figure 16.1; Singh et al., 2014). This involves a diet consisting of a special phenylalanine-restricted formula combined with low-protein foods. It is important to note that the diet for individuals with PKU cannot be completely free of phenylalanine. Phenylalanine is an essential amino acid, and a small amount is necessary for normal growth and development. Although simple in concept, these diets are extremely hard to follow. Someone like Lisa, introduced in the first case study, may only be allowed 6 grams of natural protein a day, the same amount as

Figure 16.2. Approaches to treatment of inborn errors of metabolism. Treatment can be directed at 1) substrate deprivation, limiting the influx of a potentially toxic compound; 2) supplementing the deficient product; 3) stimulating an alternate metabolic pathway; 4) providing a cofactor to activate residual enzyme activity; or 5) increasing enzyme activity by supplying the deficient enzyme, transplanting an organ with intact enzyme, or gene therapy to correct the genetic defect or to insert a normal copy of the gene.

in three fourths of a cup of pasta. The average adult female takes in 50 to 70 grams of protein a day.

Fortunately, phenylalanine-restricted diets are quite effective for individuals with PKU. A classic study showed that the IQ scores of children who began this treatment within the first month of life were around

100, whereas the scores of those initially treated later in childhood were 20 to 50 points lower (Hanley, Linsao, & Netley, 1971). A low-phenylalanine diet was initially thought to be essential only through early childhood to prevent IQ decline (Michals, Azen, Acosta, Koch, & Matalon, 1988; Waisbren, Mahon, Schnell, & Levy,

Table 16.3. Examples of treatment approaches for inborn errors of metabolism

Approaches	Disorder	Specific treatment
Substrate deprivation	Phenylketonuria (PKU)	Phenylalanine restriction
	Maple syrup urine disease	Branch chain amino acid restriction
	Galactosemia	Galactose restriction
	Tyrosinemia	NTBC/nitisinone (Orfadin)
	Gaucher disease	Miglustat (Zavesca), eliglustat (Cerdelga)
Externally supplementing the deficient product	Glycogen storage disease	Cornstarch
	Ornithine transcarbamylase deficiency	Citrulline
	Phenylketonuria	Tyrosine
Stimulating an alternative pathway	Urea cycle disorders	Phenylbutyrate (Buphenyl, Ravicti)
	Organic acidemias	Carnitine (Carnitor)
	Isovaleric acidemia	Glycine
Providing a cofactor	Biotinidase deficiency	Biotin (vitamin B ₇)
	Homocystinuria	Pyridoxine (vitamin B ₆)
	PKU	Tetrahydrobiopterin (BH ₄ , sapropterin, KUVAN)
Replacing an enzyme	Fabry disease	Agalsidase beta (Fabrazyme)
	Gaucher disease	Imiglucerase (Cerezyme)
	Morquio disease	Elosulfase alfa (Vimizim)
Transplanting an organ	X-linked adrenoleukodystrophy	Bone marrow transplant
	Ornithine transcarbamylase deficiency	Liver transplant
	Methylmalonic acidemia	Liver and kidney transplant

For entries with parenthetical text, text with initial capitalization indicates a brand name.

1987). However, “diet for life” is now the accepted approach among metabolic specialists in order to optimize cognitive outcomes, avoid executive functioning challenges, and prevent changes in brain white matter (Hood, Rutlin, Shimony, Grange, & White, 2017; van Spronsen et al., 2017; Vockley et al., 2014). See Box 16.1 for more information on metabolic specialists.

In addition to learning about the neurological risks of PKU, individuals with PKU should understand the importance of good metabolic control before conception. An elevated maternal phenylalanine level poses a serious threat for the fetus of a woman with PKU who is without dietary control (Prick, Hop, & Duvekot, 2012). Prick and colleagues’ synthesis of case reports and case series on maternal PKU showed that before newborn screening and effective treatment were available, men and women with PKU had severe intellectual disability and women did not often bear children. Their analysis showed that since effective treatment has become available, most women with PKU have been able to become mothers. Many of the women in the cohort of this study had stopped following the phenylalanine-restricted diet during childhood. Unexpectedly, almost all of the children born to these women were found to have congenital abnormalities, including microcephaly, congenital heart disease, cleft lip and palate, and gastrointestinal and urinary tract abnormalities, and they were later found to have intellectual disability. These children, however, did not have PKU; they were only carriers. Instead, the intellectual disability and other abnormalities were caused by the **teratogenic** effect (interfering with normal embryonic development) of the mother’s high phenylalanine levels on the developing fetus (Prick et al., 2012). Studies have also shown

that lowering the phenylalanine levels in pregnant mothers with PKU significantly improves the chances for typical development of offspring. As a result, it is now advised that women with PKU continue life-long dietary restriction (Vockley et al., 2014) and that tight phenylalanine control be achieved for at least 3 months prior to conception (American College of Obstetricians and Gynecologists Committee on Genetics, 2015).

Galactosemia is another disorder where substrate deprivation is used to prevent the accumulation of toxins. Infants with galactosemia develop liver failure in the first few days of life due to consumption of breast milk or lactose-containing formula. When lactose is removed from the diet, these life-threatening complications improve and infants grow as expected (Berry, 2017). However, even with adequate dietary restriction, individuals with galactosemia can exhibit speech delay, developmental delay, and premature ovarian failure (Coss et al., 2013; Frederick, Cutler, & Fridovich-Keil, 2017; van Calcar et al., 2014).

There are also nondietary approaches to substrate deprivation. One example is the inhibition of a pathway upstream to prevent the formation of toxic products behind the enzymatic block. In hereditary tyrosinemia type I, the drug NTBC, an herbicide derivative, has been found to inhibit tyrosine degradation in children who are affected, preventing the downstream formation of a toxic compound that causes liver and kidney disease and liver cancer (Chinsky et al., 2017; Das, 2017). Similarly, several substrate reduction therapies have been developed for lysosomal storage disorders, including eliglustat for Gaucher disease and miglustat for both Gaucher and Niemann-Pick C1 disease. These medications inhibit the formation of glucosylceramide,

BOX 16.1 INTERDISCIPLINARY CARE

Role of the Metabolic Dietitian

Metabolic dietitians are essential members of the care team for individuals with inborn errors of metabolism. With a sound understanding of biochemistry, these registered dietitians translate the scientific necessity of the special diets required to prevent the toxic buildup of metabolites to families, while also ensuring adequate growth and nutrition. For the majority of inborn errors of metabolism, if the toxic metabolite (e.g., phenylalanine in phenylketonuria, fat in fatty acid oxidation disorders) were completely eliminated from the diet, the individual would fail to grow appropriately and may develop overt nutritional deficiencies. Metabolic dietitians are able to individualize diet plans that prevent deficiency and promote growth while still being practical and attainable. Food is the cornerstone of many cultures. Metabolic dietitians must therefore incorporate the importance of following an extremely restrictive diet into the individual cultural beliefs and habits of families. For many families their metabolic dietitian is their first contact for any challenge related to their rare disorder. In addition to providing nutrition knowledge, metabolic dietitians often serve as insurance advocates, professional resources for school meetings, and coordinators of care related to these rare diseases.

reducing the accumulated substrate load and improving clinical outcome (Coutinho et al., 2016; Stirnemann et al., 2017). Current clinical trials are also investigating the use of genistein as a substrate reduction therapy in mucopolysaccharidosis type III, also known as Sanfilippo syndrome (de Ruijter et al., 2012).

Externally Supplementing the Deficient Product

Some children with inborn errors of metabolism are given replacements for the enzyme product they are missing. For example, the medical formulas for the treatment of PKU are enhanced in tyrosine, the product of the deficient enzyme. Tyrosine is an important precursor for a number of neurotransmitters. The goals of PKU management include both controlling phenylalanine elevations and ensuring adequate tyrosine intake (Singh et al., 2014). Similarly, the primary treatment for a group of disorders called glycogen storage diseases is uncooked cornstarch. In these disorders, individuals are unable to utilize the glycogen in their liver for energy (glucose), and cornstarch is given to provide a slow release source of glucose and prevent recurrent hypoglycemia (Kishnani et al., 2014).

Stimulating an Alternative Pathway

It is now possible to treat some metabolic disorders by stimulating an alternative pathway that detours around the enzymatic block. For example, children with inborn errors of the urea cycle cannot convert toxic ammonia to nontoxic urea. Treatment by dietary protein restriction alone has proven unsuccessful because the degree of restriction required to prevent an accumulation of ammonia does not allow a sufficient diet to permit sustained growth or prolonged survival (Shih, 1976). A different approach is to use the drug glycerol phenylbutyrate to stimulate an alternate pathway for ammonia excretion. By providing a detour around the enzymatic block and converting the ammonia to an alternate nontoxic product, phenylacetylglutamine, instead of urea, this drug allows the majority of children with urea cycle disorders to survive, although many have developmental disabilities (Rüegger et al., 2014).

Providing a Cofactor

For certain individuals with metabolic diseases, providing a large dose of a vitamin cofactor results in amplification of residual enzyme activity or enhanced enzyme stability and clinical improvement. This approach has been used most effectively in treating

children with an organic acidemia called biotinidase deficiency (Wolf, 2016). These children, who develop symptoms of acidosis and coma because of a defect in the enzyme biotinidase, show remarkable improvement if the vitamin biotin is provided at a very high (but nontoxic) dosage. The primary defect in biotinidase deficiency is the inability of the body to recycle the vitamin biotin. Biotin is an essential cofactor for a number of critical enzymes in multiple metabolic pathways. By giving these children large doses of biotin, these enzymes are normalized. In other disorders, the mutation may affect the binding site for enzyme cofactors. In some of these cases, providing large quantities of a vitamin cofactor may stabilize and even normalize enzyme activity. This type of vitamin therapy can minimize symptoms and improve outcomes for children with certain forms of another organic acidemia called methylmalonic acidemia (using vitamin B₁₂; Manoli, Sloan, & Venditti, 2005) and an amino acid disorder called homocystinuria (using vitamin B₆; Morris et al., 2017). Certain individuals with PKU respond well to tetrahydrobiopterin, the cofactor for the phenylalanine hydroxylase enzyme. Although tetrahydrobiopterin does not completely eliminate the need for a special diet in PKU, it does allow for some dietary liberalization and improved plasma phenylalanine levels (Singh et al., 2014; Vockley et al., 2014). In some disorders, providing a cofactor for treatment is so effective it eliminates all signs of disease. This can become challenging for families who culturally are suspicious of traditional medicine or question a diagnosis in their child who appears “normal.” Continuously reviewing the basis of the diagnosis and the risks of not treating may be needed to ensure that families remain compliant with treatment recommendations.

Replacing an Enzyme

The previously discussed methods of therapy use indirect approaches to improve the child's condition. Supplying the missing enzyme is a direct approach to correct the inborn error. Intravenous injections of a synthetic enzyme first proved successful in treating the lysosomal storage disorder Gaucher disease, which is associated with the accumulation of glucocerebroside in cells of the liver, spleen, and bone marrow. With severe infantile Gaucher disease, the glucocerebroside accumulates in the brain as well. Individuals who receive biweekly injections of the deficient enzyme show marked improvements, including significant shrinkage of the liver and spleen (Stirnemann et al., 2017). This enzyme, however, cannot cross the blood-brain barrier, making replacement therapy ineffective for those

children with severe infantile Gaucher disease. As of 2017, specific enzyme replacement therapy has been approved for Fabry disease; Gaucher disease; glycogen storage disease type II (Pompe disease); lysosomal acid lipase disease (Wolman); and mucopolysaccharidoses type I, II, IV, and VI (Hurler, Hunter, Morquio, and Maroteau-Lamy disease). Enzyme replacement therapy continues to be investigated as a therapy for other lysosomal storage diseases (see Box 16.2).

Another strategy that has been employed is the administration of a substitute enzyme, rather than replacement of the enzyme that is deficient. An example of this type of enzyme substitution that has shown promise is phenylalanine ammonia lyase (an enzyme produced by plants and fungi but not by humans) in the treatment of PKU. In clinical trials, intermittent subcutaneous injections of phenylalanine ammonia lyase appears to reduce the phenylalanine load and allow less severe dietary restriction (Bell et al., 2017; Sarkissian et al., 2008).

Although replacement therapy seems ideal, it is not without shortcomings. These synthetic enzymes are some of the most expensive drugs in the world. In addition, the enzyme must be injected at frequent intervals throughout the individual's life, and antibodies can develop against the foreign protein just as antibodies against insulin develop in some individuals with diabetes. Many individuals experience hypersensitivity reactions to their infusions, ranging from mild flushing and nausea to severe, life-threatening anaphylactic (allergic) reactions.

Transplanting an Organ

Some deficient enzymes can be replaced by transplanting a body organ that contains the enzyme. For example, bone marrow, umbilical cord blood, and stem cell transplantation have been performed in individuals with certain lysosomal and peroxisomal storage disorders, including juvenile metachromatic leukodystrophy, adrenoleukodystrophy, and Hurler syndrome. These disorders, marked by neurological and physical deterioration and early death, are caused by the deficiency of enzymes found in many body organs, including bone marrow cells. In a number of studies, transplantation, by providing the deficient enzyme, has resulted in improvement in symptoms and, in some cases, arrest of disease progression. It is questionable, however, whether it has an effect on brain function (Beckmann, Miller, Dietrich, & Orchard, 2017; Boelens & van Hasselt, 2016; Chiesa et al., 2016; Parini et al., 2017; Saute et al., 2016).

Liver transplantation has been associated with biochemical correction and improvement in symptoms of certain inborn errors of amino acid metabolism, most notably urea cycle disorders and maple syrup urine disease (MSUD; Diaz et al., 2014; Lichter-Konecki et al., 2016; Yu, Rayhill, Hsu, & Landis, 2015). Liver transplantation has also been used to treat severe cases of propionic acidemia (PA) and has been associated with an improvement in metabolic control, reversal of cardiomyopathy, and possible improvement in neurologic function (Nagao et al., 2013; Shchelochkov, Carrillo, &

BOX 16.2 EVIDENCE-BASED PRACTICE

Novel Therapies

Inborn errors of metabolism are very rare. Therefore, the standard treatment for most disorders is based on limited clinical studies, case reports, or expert opinion (Häberle et al., 2012; Morris et al., 2017; van Wegberg et al., 2017). Although treatments continue to be developed for inborn errors of metabolism, there are fewer therapies than are available for more common disorders. Thus novel therapies that show promise frequently are employed and can become part of standard care even before robust evidence of their efficacy is available.

Since the mid-2000s, a growing number of clinical studies in some lysosomal disorders have demonstrated the benefit of infused enzyme replacement (e.g., Gaucher disease, Pompe disease, Fabry disease, and mucopolysaccharidoses) and hematopoietic stem cell transplant (e.g., X-linked adrenoleukodystrophy [X-ALD], mucopolysaccharidoses). Notably, both Pompe disease and X-ALD had previously been nominated to be considered for addition to the Secretary of Health and Human Services Recommended Uniform Screening Panel (RUSP), in 2008 and 2012, respectively, but they were rejected at the time due to insufficient evidence. However, in 2015, based on new evidence, Pompe disease was the first lysosomal disorder to be added to the RUSP, and it was quickly followed in 2016 by the addition of X-ALD and MPS-1. Long-term outcome data of enzyme replacement or stem cell transplant in these disorders are still very limited. Even so, the addition of these three disorders to the RUSP greatly changes the paradigm of newborn screening; additional disorders will likely be added in the coming years.

Venditti, 2016). However, unlike those with a urea cycle disorder or maple syrup urine disease, individuals with propionic acidemia must continue a modified protein diet post transplant, as the risk of metabolic decompensation is not eliminated (Fraser & Venditti, 2016). Liver transplantation has also been used to treat tyrosinemia when there is liver damage and the risk for liver cancer. In some cases of methylmalonic acidemia, liver transplantation in conjunction with kidney transplantation has been effective (Niemi et al., 2015). Organ transplantation carries a risk of mortality as high as 10%–20% (Cuenca, Kim, & Vakili, 2017) and an even higher risk of morbidity. In addition, transplant recipients require immunosuppression drugs for life, and the long-range outcomes for transplant recipients is still uncertain.

Using Gene Therapy

In theory, an ideal treatment for an inborn error of metabolism would involve the insertion of a normal gene to compensate for a defective one, or correction (editing) of the defective gene. This would allow for the production of a normal enzyme, thereby permanently correcting or curing the disorder. However, in clinical research studies, progress has been slow (Hanna, Rémuzat, Auquier, & Toumi, 2017), and some trials have been associated with severe adverse events, including a death in an early trial in urea cycle disorders (Cavazzana-Calvo, Lagresle, Hacein-Bey-Abina, & Fischer, 2005; Raper et al., 2003). As of 2017, gene therapy trials have been successful in treating only a few nonmetabolic disorders, such as blood cancers (Locke et al., 2017; Maude et al., 2014), hemophilia, and hereditary blindness (Le Meur et al., 2017).

For brain-based disorders, there is the problem of getting across the blood–brain barrier. There is the potential for therapeutic application of hematopoietic stem cell gene therapy with intracerebral gene transfer (brain gene therapy) in individuals with metachromatic leukodystrophy and adrenoleukodystrophy (Eichler et al., 2017; Sevin, Cartier-Lacave, & Aubourg, 2009). Intrathecal delivery of gene therapy is also being explored (Hinderer et al., 2017).

OUTCOME

The range of outcomes in inborn errors of metabolism varies enormously. In most disorders that can be detected by newborn screening, such as PKU, children who are affected have usually done well. Their IQ generally falls within the average range, if somewhat lower than that of their parents. They are, however, at increased risk for having learning disabilities and ADHD (Jahja et al.,

2017; Palermo et al., 2017; Singh et al., 2014; van Spronsen et al., 2017; Vockley et al., 2014). Less favorable outcomes occur in other inborn errors of amino acid and organic acid metabolism. Although these children are surviving longer, many manifest developmental disabilities. Among children with metabolic disorders associated with progressive neurological disorders, such as certain lysosomal storage diseases, there has been only limited improvement in mortality and morbidity.

SUMMARY

- Although inborn errors of metabolism are rare, their consequences are often devastating.
- Therapy is effective for a number of these disorders.
- Children who are affected often must continue treatment for the rest of their lives, which may prove difficult.
- For therapy to succeed, it must be started early.
- The expansion in the number of disorders that are tested by newborn screening bodes well for early identification and treatment with the possibility of improved outcome.

CHAPTER 17

Speech and Language Disorders

Barbara L. Eckelman and Barbara A. Lewis

Upon completion of this chapter, the reader will

- Differentiate among children with various speech sound disorders, namely articulation, phonology, and apraxia
- Differentiate among children with various language disorders, namely receptive and expressive language disorders involving phonological awareness, morphology, syntax, semantics, and pragmatics
- Identify the possible etiological bases for speech and language disorders, their prevalence, and common comorbid conditions
- Employ evidence-based practices for the treatment and remediation of speech and language disorders
- Discuss prognostic indicators for outcomes and variables associated with persistent speech and language disorders

For most children, the basics of speech and language emerge effortlessly over the first 3 years of life, progressing from babbling to first words to simple sentences, with further complexities of language developing well into later childhood. Yet for other children, developmental milestones for speech and language are delayed and not achieved according to age expectations. Some of these children go on to have significant speech, language, and learning disabilities that require intervention and can have lifelong social-emotional, academic, and occupational consequences. These individuals present with various profiles of speech, language, and learning impairments. This chapter will review the diagnosis and treatment of these disorders, applying evidence-based practices.

■ ■ ■ CASE STUDY

Steve's parents were concerned that his speech development was delayed. He was late to talk, and his first words contained mostly vowel sounds, in particular the "uh" sound. When Steve was 2½ years old, he attended a preschool setting for 2 days each week and played appropriately with his peers. However, although Steve made frequent attempts to communicate, his speech remained unintelligible, especially to unfamiliar listeners. The preschool teacher encouraged his parents to have him tested, so the parents spoke to Steve's pediatrician about their concerns, and the pediatrician referred the family to the local early intervention program (see Chapter 31) through which Steve received

a speech-language evaluation. The pediatrician also recommended an audiological evaluation. The audiologist and speech-language pathologist (SLP) evaluated Steve when he was 2 years, 10 months of age. The audiologist ruled out hearing loss as the basis for Steve's speech-language delays (see Box 17.1 for a discussion of the roles of the multidisciplinary team in Steve's care).

The SLP administered the Preschool Language Scale–Fifth Edition (PLS-5; Zimmerman, Steiner, & Pond, 2011), the Goldman-Fristoe Test of Articulation–Third Edition (GFTA-3; Goldman & Fristoe, 2015), and the Clinical Assessment of Articulation and Phonology–Second Edition (CAAP-2; Secord & Donohue, 2014). Steve scored above the mean in the average range on the PLS-5 (suggesting well-developed general language skills), but he scored 2 standard deviations (SDs) below the mean on the GFTA-3 and CAAP-2 (suggesting specific impairments of articulation). Steve's mother completed the Vineland Adaptive Behavior Scales–Third Edition, Parent Interview (Vineland-3; Sparrow, Cicchetti, & Saulnier, 2016). The test results confirmed a speech sound disorder (SSD; an articulation and phonological disorder) and a spoken language disorder (SLD). Interestingly, Steve's socialization score on the Vineland-3 was high. Steve's SLD qualified him for preschool early intervention services through his public school (see Chapter 33).

Steve received speech services one time per week from age 2 years, 10 months to 4 years, 2 months. The intervention focused on correcting multiple speech sound errors, including omissions, syllable reductions, substitutions, cluster reductions, and fronting of back sounds. Both articulation and phonological approaches were implemented for therapy.

Thought Questions:

When a child has a significant speech delay, how can professionals best develop an “action plan” for characterizing the nature and possible causes of the delay, and what bearing does this have on designing a plan for evaluation and treatment? For children diagnosed with a speech or language disorder in preschool, what sort of problems may develop as they get older, and what can professionals do to monitor for these problems?

DEFINITIONS, DESCRIPTIONS, AND CLASSIFICATIONS

Speech and language disorders can be classified as speech sound disorders and spoken language disorders, both of which are described in this section. Diagnostic criteria of communication disorders according to the American Psychiatric Association's *Diagnostic*

BOX 17.1 INTERDISCIPLINARY CARE

Multidisciplinary Team Members Involved in Steve's Care

Pediatrician: The pediatrician follows the child's health and development over time. The pediatrician agrees that Steve's spoken language disorder warrants a speech-language evaluation at this time. He also refers Steve to an audiologist to rule out hearing loss (either sensorineural or conductive; see Chapter 26) as the cause for his speech-language delays.

Audiologist: The audiologist tests hearing acuity. The audiologist wants to determine whether Steve has a sensorineural hearing loss or a conductive hearing loss due to fluid build-up in his middle ear. Steve's air and bone conduction thresholds and tympanometry test results show excellent hearing.

SLP: The SLP works to improve Steve's speech and language skills (listening, speaking, reading comprehension, and written expression), memory, retrieval, and residual speech sound errors.

Occupational Therapist: The occupational therapist's goals for Steve are to improve pencil grip and letter formation (place, manner, spacing, and sizing).

Learning Specialist: The learning specialist works to improve Steve's reading (decoding, fluency, and comprehension) and writing (spelling and written expression) skills.

Psychiatrist: The child psychiatrist will determine if Steve has an attention deficit and will rule out other psychological factors such as depression and anxiety. A psychiatrist's treatment may be focused on medication management of ADHD.

Psychologist: The psychologist will assess Steve's cognitive abilities and learning skills. He will help Steve succeed academically, behaviorally, and socially in school.

and *Statistical Manual of Mental Disorders—Fifth Edition* (DSM-5; APA, 2013) are also briefly addressed.

Speech Sound Disorders

Some children have difficulty learning and producing speech sounds. Although there is great variability in the typical rate at which children learn speech sounds, some children lag significantly behind their peers in producing intelligible speech. These children are said to have a **speech sound disorder (SSD)**. Children with an SSD may not be intelligible to family members or friends.

Children may have difficulty with speech sounds for different reasons. Some children have difficulty learning the sound system of their language and the rules for combining sounds. These children have a **phonological disorder**. Other children have difficulty producing the speech sounds. They may substitute one sound for another, omit a sound altogether, or distort a sound. These children have an **articulation disorder**. Many children, such as Steve in the case study, have a combination of a phonological disorder and an articulation disorder.

There is a developmental sequence of speech sound acquisition, with sounds that are more easily produced and more frequently used in the language mastered first. Early sounds are /m/, /b/, /y/, /n/, /w/, /d/, /p/, /d/, and /h/. Next, /t/, /ng/, /k/, /g/, /f/, /v/, /ch/, and /j/ are learned. Later developing sounds are /sh/, /th/, /s/, /z/, /l/, and /r/. Consonant clusters (/sp/, /st/, /sk/, /br/, /bl/, /spr/, /str/, and /skr/) are also typically mastered later. By

8 years of age, most children employ the adult speech sound system with few or no sound errors in conversation. Common speech sound errors are described with examples in Table 17.1.

Sometimes the cause for an SSD is readily identifiable. Children with hearing loss, cleft palate, cerebral palsy, and other medical conditions typically present with SSDs because of their sensory impairments or because of physical limitations that affect their ability to generate accurate speech sounds. However, for the majority of children with SSDs, the cause of the speech difficulty is unknown. Professionals have speculated as to possible reasons for SSDs. For example, some children may have difficulty discriminating and processing different speech sounds and therefore do not learn the sounds correctly (**phonological processing deficits**). Other children may not form accurate representations of the sounds in the brain or may have trouble storing them in memory (weak phonological representations). Another group of children may have difficulty with planning and executing a motor program for producing the speech sounds (**childhood apraxia of speech** [CAS]), and still another group may have motor incoordination or weakness of the muscles needed to articulate intelligible speech (**developmental dysarthria**). It is important for every child with speech sound difficulties to have a comprehensive evaluation performed by a licensed and certified SLP to determine the specific problems that the child has and to develop an appropriate therapy plan to remediate these difficulties.

Table 17.1. Examples of speech sound errors

Error	Description	Examples
Omissions	Deletion of a sound within a word	“truck” to “-uck”
Substitutions	Substituting one sound in a word for another	“tar” to “kar”
Distortions	Substituting a typical sound for an atypical/idiosyncratic sound	Pronouncing the “s” sound around the side of the tongue rather than over the top of the tongue
Additions	Adding extra sounds to words	“dog” to “dogga”
Fronting of back sounds	Sounds typically produced in the back of the mouth are moved to the front	“goat” to “doat”
Backing of front sounds	Sounds typically produced in the front of the mouth are moved to the back (less common than fronting)	“dog” to “gog”
Final consonant deletion	Final consonant sounds are dropped in multiple words	“feet” to “fee-”
Initial consonant deletion	Initial consonant sounds are dropped in multiple words	“dig” to “-ig”
Cluster reductions	Reduction of two adjacent consonant sounds to one	“snake” to “-nake”
Syllable reductions	Syllables dropped from words	“banana” to “-nana”
Gliding	Liquid sounds (L & R) are changed to glides (Y & W)	“yellow” to “yeyo” “leg” to “weg”
Metathesis	Order of sounds in a word are changed (with or without sound substitutions)	“spaghetti” to “pasketti”

As defined by the American Speech, Language, and Hearing Association (ASHA), CAS is a neurological childhood (pediatric) SSD in which the precision and consistency of movements underlying speech are impaired in the absence of neuromuscular deficits. CAS may occur as the result of known neurological impairment, in association with complex neurobehavioral disorders of known or unknown etiology, or as an idiopathic neurogenic SSD. The core impairment in motor planning the spatiotemporal parameters of movement sequences results in errors in speech sound production and **prosody** (the melody, flow, and rhythm of speech). Children with CAS may have difficulty moving from one articulatory configuration to another (Strand, 2017). Comorbid spoken language disorders and specific reading disabilities are often observed in children with CAS (ASHA, 2007). CAS is rare with prevalence estimates between 0.125% (Shriberg, Aram, & Kwiatkowski, 1997) and 1.0% (Yoss & Darley, 1974).

Children with CAS often present with early developmental difficulties that may be indicative of suspected CAS. These include problems with feeding as an infant, little vocal play or babbling, little imitation in infancy, a family history of speech disorders, delayed onset of language, and gross and fine motor incoordination. The diagnostic criteria for CAS are controversial, and often a course of therapy is required before a diagnosis is made. Exclusionary criteria include sensory disorders, cognitive impairment, receptive language deficit, emotional/pragmatic disorder, and poor muscle tone. Hallmark characteristics include groping movements of the articulators and trial-and-error behaviors to produce speech sounds, deviant speech development, receptive abilities better than expressive abilities, inconsistent errors, prosody disturbances, and slow progress in therapy. Speech characteristics include unusual errors not found in children with other types of SSD, a large percentage of omission errors, difficulty producing and maintaining appropriate voicing (switching a consonant sound that engages the vocal cords for one that does not, or vice versa; e.g., /b/ for /p/), vowel and diphthong errors, difficulty sequencing speech sounds and syllables, difficulty with nasality and nasal emission, groping behaviors and silent posturing, prosodic impairments, and difficulty identifying rhymes and syllables (Murray, McCabe, Heard, & Ballard, 2015).

It is important for every child with speech sound difficulties to have a comprehensive evaluation performed by a licensed and certified SLP to determine the specific problem(s) that the child has and to develop an appropriate therapy plan to remediate these difficulties.

Spoken Language Disorders

ASHA defines a **spoken language disorder (SLD)** as “a significant impairment in the acquisition and use of language across modalities (e.g., speech, sign language, or both) due to deficits in comprehension and/or production across any of the five language domains (i.e., phonology, morphology, syntax, semantics, pragmatics)” (<https://www.asha.org/Practice-Portal/Clinical-Topics/Spoken-Language-Disorders/> pg1). An SLD may occur in isolation or in combination with other developmental disorders such as autism spectrum disorder (ASD), Down syndrome, intellectual disabilities, and many other neurodevelopmental disorders. Some SLDs are acquired as in the case of traumatic brain injury. A child with SLD may present with **receptive language** (comprehension) delays and/or **expressive language** (production) delays.

Children with SLD are heterogeneous and often exhibit different profiles of language skills across the domains of **semantics** (meaning), **syntax** (structure), morphology (smallest units of meaning), **pragmatics** (rules and conventions), and **phonology** (sound system) (see Table 17.2 for detailed definitions). An assessment by an SLP will determine if language skills are delayed but following a typical developmental course or if they are deviant (disordered) and presenting with an unusual pattern of language errors. For example, some children with an SLD present with specific problems with syntax and phonology while semantics and pragmatic language skills remain intact. Other children have a severe communication deficit that includes non-verbal as well as verbal communication. See Box 17.2 for more information on comorbid language disorders.

Diagnostic Criteria

The *DSM-5* provides diagnostic criteria and features for a broad range of developmental disorders that may involve speech and language disorders such as autism spectrum disorder (ASD). It includes information on differential diagnosis, comorbid disorders, and risk factors.

The specific diagnostic category of communication disorders includes language disorder, SSD, childhood-onset fluency disorder, social communication disorder, and unspecified communication disorder. The unspecified communication disorder is assigned when symptoms are present but do not meet a sufficient number of the diagnostic criteria to warrant a more specific diagnosis.

The *DSM-5* has made several controversial changes to the diagnosis of communication disorders, including

Table 17.2. Speech and language definitions, descriptions, and classifications

Phonology	The sound system of a language and the rules that govern the sound combinations
Phonological awareness	Metalinguistic awareness of all levels of the speech sound system, including word boundaries, stress patterns, syllables, onset-rime units, and phonemes; a more encompassing term than phoneme awareness, which is the explicit understanding that words are composed of phonemes (i.e., segments of sound smaller than a syllable) plus the knowledge that each of these phonemes has distinctive features (Moats, 2010; Moore-Brown & Montgomery, 2001)
Phonological working memory	Temporary storage of speech codes in memory that allows the meaning of language to be extracted and stored in longer term memory (Moats, 2010).
Phonological retrieval	Retrieval of the phonological form of a word from long-term memory; refers to the mental act of formulating and pronouncing the word (Moats, 2010).
Prosody	The melody, flow, and rhythm of spoken language; melodic changes in syllable stress, pitch, loudness, and duration (Plante & Beeson, 2004)
Morphology	The study of morphemes, the smallest units of language that have meaning; free morphemes (cat, dog, me, etc.) can stand alone to convey meaning and cannot be reduced any further without losing meaning; bound morphemes (-ing, -s, -er, etc.) cannot stand alone and must be attached to a free morpheme to convey meaning (Shipley & McAfee, 1998)
Syntax	The rule system governing sentence formation; the study of sentence structure (Moats, 2010)
Semantics	The study of the meaning of language, including meaning at the word, sentence, and conversational levels; also known as content (Shipley & McAfee, 1998)
Pragmatics	The system of rules and conventions for using language and related gestures in social contexts; the study of that rule system (Moats 2010)
Discourse	The organization of sentences into larger cohesive communication units and the ability to process and formulate these units (Moats, 2010)
Metalinguistics	The ability to think about and analyze language in a critical manner, including the ability to understand humor, multiple meanings, inferences, and figurative language (Vinson, 2012)
Receptive language	The individual's ability to understand and process language (Kaderavek, 2011)
Expressive language	The language a person produces spontaneously, without imitating another person's verbalizations (Pence Turnbull & Justice, 2017)

BOX 17.2 EVIDENCE-BASED PRACTICE**Comorbid Language Disorders Associated with Speech Sound Disorders**

About 50% of preschool children with speech sound disorders (SSDs) have comorbid language impairment. That is, in addition to speech sound deficits, these children may have problems with vocabulary, grammar, morphology, and/or social language. Language impairments may be limited to expressive language or may involve both receptive and expressive language. Children with early speech and language deficits are at risk for reading, spelling, and written language difficulties at school age and adolescence. Spoken language skills lay the foundation for reading and written language.

Lewis and colleagues (2015) followed 140 children with SSDs identified during early childhood through adolescence. Individuals with an SSD and comorbid language impairment had poorer literacy skills than those with SSD only or no history of SSD. Risk factors for language and literacy problems in adolescence included persistent SSD, history of early language impairment, and lower nonverbal cognitive ability.

- These results underscore the importance of completing a comprehensive evaluation by kindergarten with at-risk children who have already been identified as toddlers as having speech language delays/disorders.
- These results underscore the dangers of a “wait and see” approach to servicing children with suspected speech language delay.

the addition of social communication disorder and the elimination of specific language impairment (Rice, 2016). Individuals who present with other disorders described in the *DSM-5* such as ASD, specific learning disability, attention-deficit/hyperactivity disorder (ADHD), and intellectual disability may also meet the criteria for a communication disorder and should be assessed by an SLP (Paul, 2013).

■ ■ ■ CASE STUDY

Steve was discharged from speech-language therapy when he was 4 years, 2 months of age because his speech sound production skills were age appropriate. His classmates could understand his speech, and his social communication and play skills were excellent. When Steve was 5 years old and entering kindergarten, his mother expressed concerns about his language development (vocabulary and syntax) and the impact his early SSD would have on literacy development. His mother also noted that Steve's speech had a "stuttering" quality because he had trouble finding the right words, repeated words and partial

phrases, and often revised his verbal output. Telling a story seemed to be a laborious process for him.

The school SLP administered three subtests (Sentence Structure, Word Structure, and Expressive Vocabulary) from the Clinical Evaluation of Language Fundamentals Preschool–Second Edition (CELF-P2; Semel, Wiig, & Secord, 2004) and collected a brief speech sample. The school SLP provided no specific information for receptive versus expressive language, syntax, semantics, or early literacy skills. Based on the analysis of the speech sample, the SLP ruled out the diagnosis of stuttering (see Box 17.3 for a discussion comparing normal dysfluency and persistent stuttering). Steve's CELF-P2 Core Language score of 98 placed him within the average range. The special service team did not qualify him for continued support services in kindergarten.

Steve's first-grade teacher contacted special services mid-year because she was concerned about Steve's language and learning development. In the area of listening, she noted Steve had trouble following spoken directions and remembering what was said and that he often asked for clarifications. In the area of speaking,

BOX 17.3 EVIDENCE-BASED PRACTICE

Normal Dysfluency or Persistent Stuttering?

Speech-language pathologists (SLPs) and pediatricians are often confronted with the dilemma of determining if a young preschool child (usually between 2 and 4 years of age) is presenting with early signs of stuttering or if the child is exhibiting normal dysfluencies typical of young children who are acquiring language. A common practice is to "wait and see" as normal dysfluencies generally disappear between 6 and 12 months from onset. However, this policy may delay intervention for children who will become persistent stutterers. Some speech characteristics of normal dysfluencies that may assist in distinguishing these from true stuttering behaviors include whole phrase repetition (instead of syllable repetitions), lack of tension, prolongations and blocking (inability to produce a word; i.e., getting "stuck"), and a negative family history for stuttering (Coleman, 2013).

Recent research also suggests that language characteristics may indicate risk for true stuttering. In one study, children with more rapid growth rates of productive syntax recovered more often than children with slower rates (Leech, Ratner, Brown, & Weber, 2017). Another study of children between 28 and 43 months of age demonstrated that as grammatical abilities increased, dysfluencies decreased (Hollister, Van Horne, & Zebrowski, 2017). Smith and Weber (2017) have proposed a multifactorial dynamic pathway theory of the development of stuttering that incorporates motor, linguistic, emotional, and genetic/epigenetic factors.

- These findings suggest that a "wait and see" policy to differentiate normal dysfluencies from persistent stuttering in young children is not appropriate.
- SLPs should consider characteristics of the dysfluencies as well as other factors, such as language development, family history of stuttering, gender of the child, and level of parent concern when determining whether to intervene.
- Recent studies suggest that early persistent stuttering may be related to slower language growth. Children with dysfluencies should be monitored for language delays that may impact later academic performance.

she indicated difficulties with asking and answering questions, use of vocabulary, describing and expressing thoughts, use of appropriate grammar and sentence structure, and difficulty articulating sounds. In the area of reading, she reported that Steve had trouble with sound play (rhyming, letter names, and letter sounds), sounding out words, understanding and explaining what was read, and remembering details. In the area of writing, she noted Steve did not have a proper pencil grip and that his handwriting was below grade-level expectations.

A multifactored evaluation was completed at his school and an evaluation team report (ETR) was written. In sum, the results of testing indicated multiple areas of weakness: expressive language (produced language or speech), **phonological processing** (including phonological awareness, memory, and retrieval; see Table 17.2), auditory processing, reading, writing, and speech sound production.

The school occupational therapist administered the Beery-Buktenica Developmental Test of Visual-Motor Integration—Sixth Edition (VMI-6; Beery, Buktenica, & Beery, 2010). Steve's scores for visual-motor integration and motor coordination fell in the below-average range. His score for visual perception fell in the above-average range. The special education team developed an individualized education program (IEP) (see Chapter 33) for Steve that described the services he needed in order to access the curriculum. He was scheduled to work with the SLP, learning specialist, and occupational therapist both within and outside the general education classroom.

PREVALENCE AND EPIDEMIOLOGY

Speech and language disorders are highly prevalent in young children. The National Center for Health Statistics reported that in 2012, 7.7% of children 3–17 years of age had a communication disorder based on interviews of parents and caregivers (Black, Vahratian, & Hoffman, 2015). Speech problems were the most common (5%), followed by language problems (3.3%). One third of the children 3–10 years of age and one fourth of the children 11–17 years of age had comorbid disorders. Communication disorders were more prevalent in young children (11% at 3–6 years of age) than older children (9.3% at 7–10 years and 4.9% at 11–17 years) and more common in boys (9.6%) than girls (5.7%).

Speech Sound Disorders

SSDs are one of the most common types of communication disorders in children, with prevalence rates of 15.6% at 3 years of age (Campbell et al., 2003), 3.4% at 4 years of age (Eadie et al., 2015), and 3.8% at 6 years of age (Shriberg, Tomblin, & McSweeney, 1999). At 6 years

of age, 25% of children with early SSD continue to present with SSD. For most individuals, the SSD resolves by early grade school (approximately 8 years of age), but for others speech sound errors persist into adolescence and beyond (persistent SSD). More than one half of children with early SSD, as well as the majority of those with persistent SSD, encounter later academic difficulties in language, reading, and spelling (Lewis et al., 2015). Rates of persistent SSD vary based on age of assessment, criteria for persistent SSD, and whether the sample is clinically based or population based. One population-based estimate of persistent SSD is 3.6% of children at 8 years of age (Wren, Miller, Peter, Emond, & Roulstone, 2016).

Spoken Language Disorder

A large population-based study (Tomblin et al., 1997) examined 7,218 kindergarten children and reported a 7.4% overall prevalence rate of SLDs (8% in boys and 6% in girls). Another study reported that 7.58% of 4–5 year olds entering school have a clinically significant language disorder of unknown cause that adversely impacts learning (Norbury et al., 2016). Children whose SLD persists to the age of literacy acquisition are more likely to have difficulty learning to read (Snowling, Duff, Nash, & Hulme, 2016). The comorbidity of SSD and SLD has been reported in 1.3% of children (Shriberg et al., 1999). In children with SSD and SLD, 6% to 21% have been found to have receptive language disorders, and 38%–62% have been found to have expressive language disorders (Shriberg & Austin, 1998). Rates are higher for children with persistent disorders. For example, 11%–15% of children with persistent SSD have SLD, and 5%–8% of children with persisting SLD have SSD.

Comorbid Disorders

Other disorders such as specific reading disability (SRD; see Chapter 20) and ADHD (see Chapter 19) are often comorbid with speech and language disorders (Figure 17.1 illustrates the relationship between spoken and written language). The prevalence of SRD is estimated at 7% when defined as 1.5 SD below the mean on a test of reading achievement and 9% in a clinically ascertained population (Pennington & Bishop, 2009; Peterson & Pennington, 2012). Approximately one half of individuals with SLD meet the criteria for SRD (Catts, Fey, Tomblin, & Zhang, 2002; Snowling, Bishop, & Stothard, 2000), while fewer children with SSDs meet the criteria for SRD. Children with combined SSD and SLD are more likely to have SRD than those children

Figure 17.1. Model of speech/language and learning skills, which depicts the relationship between spoken and written language. The phonology of spoken language is related to reading decoding and spelling, and spoken language skills (syntax, semantics, pragmatics, discourse, and metalinguistics) contribute to reading comprehension skills and written expression. Also shown is the relationship between reading decoding and spelling and reading comprehension and written expression.

with SSD alone (Lewis et al., 2015). The high rates of comorbidity of SSD, SLD, and SRD are not surprising as they all involve components of language, especially phonology (see Box 17.4).

ADHD is often comorbid with SSD, spoken language disorder (SLD), and specific reading disability

(SRD). Clinical studies have found that the comorbidity of SLD and ADHD ranges from 16% to 24% (Mueller & Tomblin, 2012). This rate drops to 3.3% of adolescents with persistent SLD (Snowling et al., 2006). Approximately 30% of children with SRD also have ADHD (International Dyslexia Association, 2008), and

BOX 17.4 EVIDENCE-BASED PRACTICE

Phonological Awareness and Reading Disorders

Individuals with speech sound disorders with and without an additional language impairment perform more poorly than controls on phonological awareness measures (Skebo et al., 2013). Children with more atypical or nondevelopmental speech sound errors (e.g., deletion of initial consonants) have more difficulty with phonological awareness tasks than children with typical errors (developmental /s/, /z/, /l/, and /r/; Preston & Edwards, 2010). Deficits in phonological awareness have been identified as one of the strongest early predictors of reading disorders (Wagner, Torgesen, Rashotte, & Pearson, 2013). Phonological awareness is the ability to manipulate phonemes in spoken words as well as the awareness of the sound structure of language.

- These results suggest that phonological awareness skills should be evaluated in kindergarten to identify children at risk for reading difficulties.
- These results indicate that developing phonological awareness skills should be part of the kindergarten curriculum.

language impairment is highly correlated with ADHD, with rates greater than 40% of children with combined SRD and ADHD (Helland, Posserud, Helland, Heimann, & Lundervold, 2016).

■ ■ ■ CASE STUDY

In fourth grade, Steve had no residual speech sound errors. His phonological awareness, phonics skills, and spelling skills were adequate. He wrote neatly with a proper pencil grip. However, Steve's reading vocabulary was limited, and he had difficulty understanding what he read and expressing himself in writing. Although Steve used simpler sentences to express himself, his social communication skills were excellent. Steve had an excellent work ethic, and he always turned his homework in on time even though he had to spend many more hours than his classmates to complete assignments. Because of Steve's working memory and processing limitations, his teacher was concerned he might have a comorbid ADHD (see Chapter 19 for a discussion of ADHD and comorbid language disorder). A child psychiatrist specializing in ADHD assessed Steve and ruled out an attention deficit. Based on Steve's latest ETR, he continues to qualify for an IEP to receive services from the SLP. The intervention is focused on written expression, vocabulary development, and reading comprehension.

ETIOLOGY

The etiology of speech and language disorders is complex due to the many neurobiological, anatomical, genetic, environmental, and cognitive factors that impact speech and language development. Some children have medical conditions that disrupt the acquisition of speech and language such as cleft lip and palate, hearing impairment (see Box 17.5 for a discussion of the impact of chronic otitis media on speech and language development), cerebral palsy, and syndromes with associated intellectual disabilities and cranial facial abnormalities. However, for many children with speech and language disorders, no known etiology for the disorder is identified; these cases are sometimes referred to as idiopathic. Table 17.3 presents risk factors associated with speech and language disorders.

Neurological Foundations of Speech and Language

Advances in neuroimaging techniques have provided new noninvasive methods to study speech and language processing in the brain (see Chapter 8). Studies utilizing these technologies have identified differences in brain structures as well as differences in language processing in children with speech and language

BOX 17.5 EVIDENCE-BASED PRACTICE

Middle Ear Infections and Speech-Language Development

There is a substantial body of research on the impact of otitis media with effusion (OME) on speech and language development (Casby, 2001). Approximately 66% of young children by 3 years of age and 80% of children by 4 years of age experience OM. OME results in a temporary mild to moderate hearing loss at an age when language skills are emerging. Since the hearing loss is fluctuating with normal hearing between OME episodes, the child may be exposed to inconsistent models of speech and language that result in a failure to encode clear phonological representations.

Longitudinal studies have demonstrated early speech and language delays in children with chronic OME around 2 years of age, but these delays are no longer apparent at 7 years of age (Zumach, Gerrits, Chenault, & Anteunis, 2010). However, recent studies have demonstrated a relationship between OME and literacy, presumably due to poor phonological awareness skills (Carroll & Breadmore, 2018). A study of Australian indigenous school children indicated that OME may be one factor affecting literacy skills (Timms, Williams, Stokes, & Kane, 2014).

- Children's hearing should be screened routinely until 7 years of age, and hearing should be tested at any age when speech, language, or learning problems are identified.
- Although early OME has not been demonstrated to impact school-age language skills, it is important to monitor early hearing and provide preschool therapy for children with delays to ensure kindergarten readiness.
- OME may be related to poorer literacy skills in at-risk populations.
- Articulation therapy is highly effective after the OM has resolved and hearing acuity returns.

Table 17.3. Risk factors associated with speech and language disorders

Examples	
Prenatal	Infections of amniotic fluid or membrane, maternal drug or alcohol use, maternal kidney infection, multiple gestation, placental bleeding, excessive or insufficient amniotic fluid, and maternal preeclampsia (hypertension, proteinuria, edema) (see Chapter 3)
Perinatal	Long labor, uncontrolled delivery, abnormal presentation of the infant, cesarean section, fetal distress, placental abnormalities, any perinatal condition that causes brain injury (see Chapter 3)
Neonatal	Low or unusually high birth weight, prematurity, hyperbilirubinemia, poor feeding, any kind of infection, physical anomalies (see Chapter 5)
Medical and genetic	Prolonged hospitalizations, syndromes such as Down syndrome, fragile X, Prader-Willi, neurological abnormalities (see Chapters 1, 3, and 15)
Environmental factors	Family environment, maternal education (affects mother's interaction with the child), low SES, toxins such as lead (see Chapter 2)
Cognitive factors	Inefficient auditory processing, poor verbal memory, learning disabilities, intellectual disability (see Chapters 14 and 20)
Sensory deficits	Congenital or acquired hearing impairments including sensory neural hearing loss, conductive hearing loss including chronic otitis media with effusion (see Chapter 26)

disorders. Structural differences include asymmetry of brain structures, differing amounts of white matter in the brain, and additional gyri in the frontal and temporal lobes. Language-processing differences identified include an increase in the number of brain structures activated, atypical bilateral brain activation patterns, hypo-activation in the frontal and parietal lobes, and neural differences in response to auditory stimuli (Hickok, 2009; Price, 2010; Tkach et al., 2011).

Although these technologies promise exciting new developments in the understanding of the neurological bases of speech and language, some limitations should be noted. For example, it is not known whether these brain differences cause the speech and language disorder or whether having a speech and language disorder results in these observed differences. In addition, other developmental disorders present with similar brain differences, and therefore these neurological differences are not unique to speech and language disorders. Finally, other family members may share these brain differences but do not report a history of speech and language disorders suggesting that other factors, such as genetics, may contribute to language skills (Paul & Norbury, 2012).

Genetic Bases of Speech and Language Disorders

Some children with speech and language disorders have been diagnosed with genetic syndromes. However, most children who are referred to SLPs have no known genetic basis for their disorder, although case histories often indicate other family members with speech, language, and reading difficulties. Since the mid-1990s, advances in genetic technology have

allowed for genome-wide studies of speech and language disorders. These studies have identified some candidate genes for speech and language disorders as well as conditions that are often comorbid such as reading disorders and ADHD (Lewis et al., 2006; Worthey et al., 2013).

One such gene, the *FOXP2* gene, which is located on chromosome 7q13, was discovered in a large British family referred to as the “KE family” (Lai, Fisher, Hurst, Vargha-Khadem, & Monaco, 2001; Morgan, Fisher, Scheffer, & Hildebrand, 2017). Affected family members, spanning three generations, presented with orofacial apraxia, persistent SSDs, impairments in IQ, language disorders, and reading difficulties. Neuroimaging studies confirmed that the *FOXP2* gene influenced neurodevelopment in multiple areas of the brain that support speech and language. However, mutations in *FOXP2* are rare (Morgan et al., 2017; Reuter et al., 2017; Vargha-Khadem, Gadian, Copp, & Mishkin, 2005).

Other candidate genes were subsequently identified (*KIAA0319*, *TTRAP*, *DCDC2*, *BDNF*, *DRD2*, *AVPR1*, *CYP19A1*, and *CNTNAP2*, among others) that are also known to influence neurodevelopment and are associated with multiple developmental disorders, including speech, language, reading, and ADHD (Newbury & Monaco, 2010). There is no single gene responsible for the majority of cases of speech and language disorders. Heterogeneous effects of risk genes may act alone or together to give rise to multiple profiles of speech and language skills that may culminate in the same diagnosis and general impairment on the surface. The nature and severity of the disorder might vary at different developmental stages as genes may be turned on and off during the life span. The environment may act in concert with genes to give rise to cognitive skills

(endophenotypes) such as phonological awareness skills, memory, vocabulary, and cognitive abilities. These endophenotypes contribute to multiple disorders such as SSDs, SLD, or SRD. Environmental factors such as early intervention or speech-language therapy might modify the resulting phenotype.

The SLP is often the first professional to treat a child with a developmental delay. A working knowledge of genetics may assist the SLP in making referrals to geneticists and genetic counselors when indicated. Knowledge of the features of genetic conditions may result in accurate prognosis, targeted interventions, and appropriate educational plans for the child.

ASSESSMENT AND DIAGNOSIS

The assessment, diagnosis, and remediation of speech and language disorders is a multimodal process. It involves evaluating speech sound and language skills in the contexts of speaking, listening, reading, and writing. The diagnostic process is not conducted in isolation; rather, information from parents, pediatricians, teachers, psychologists, and special educators, as available, is considered during part of the diagnostic process. Pediatricians are responsible for following and documenting a child's developmental history and managing medical needs. Psychologists and psychiatrists provide information about a child's intelligence, attention, and socioemotional development. Learning specialists and teachers provide information about a child's in-class reading and writing history in relation to same-age peers. There are several models for how the assessment team functions together (see Chapter 30).

Test battery selection depends on the age of the child being tested, the time allotted for testing, and the areas of concern. Specialists working in hospitals or schools often carry heavy case loads and do not have the luxury of time; therefore, it is sometimes necessary to shorten the test protocol. In these instances, it is important to get a sampling across skill areas to identify discrepancies.

Screening tools are often used to identify children who need further assessment and what specific areas are of greatest concern. The percentage of children who fail a screening test varies greatly depending on the age of the child who is screened and the screening tool employed. Before choosing a screening measure, the sensitivity (the degree to which a measure identifies a child as having a problem) and the specificity (the degree to which a measure accurately identifies a child as not having a problem) should be addressed. There are informal screening measures and formal, standardized screening tests. Informal measures may include collecting a language sample through conversation

with the child; asking the child to perform simple tasks, such as counting to ten or writing his name; or asking the child to answer simple questions, such as his age or the name of his teacher. Formal screenings evaluate single word articulation, phonology, and other levels of receptive and expressive language, comparing the child's test performance with a normative sample or criterion. Examples of early childhood screenings include the CELF-5 Screening Test (Wiig, Semel, & Secord, 2013b) and the Fluharty-2 (Fluharty, 2001).

In the case study, Steve was administered a comprehensive battery in Grades 1, 4, and 11. Tests were selected and administered to assess cognition (Wechsler Intelligence Scale for Children–Fifth Edition [WISC-V]; Wechsler, 2014); receptive and expressive foundational language at the phonological, syntactic, and semantics levels (CELF-5; Wiig & Secord, 2013a; Peabody Picture Vocabulary Test–Fourth Edition [PPVT-4]; Dunn & Dunn, 2007; Expressive Vocabulary Test–Second Edition [EVT-2]; Williams, 2007; Test of Auditory Processing Skills–Third Edition [TAPS-3]; Martin & Brownell, 2005; Comprehensive Test of Phonological Processing–Second Edition [CTOPP-2]; Wagner, Torgesen, Rashotte, & Pearson, 2013); higher-level language at the pragmatic and semantic levels (CELF-5 Metalinguistics; Wiig & Secord, 2014); and learning (Woodcock-Johnson IV Tests of Achievement [WJ IV ACH]; Schrank, Mather, & McGrew, 2014).

Steve's full-scale IQ on the WISC-V fell in the average range across time periods. In first grade, Steve's expressive language, auditory processing, phonological awareness, and memory skills fell well below his full-scale IQ. His speech sound deficit interfered with the development of adequate phonological awareness skills, which, in turn, negatively impacted his basic reading and spelling development. In addition to compromised phoneme-grapheme (sound-letter) knowledge, Steve's lower reading comprehension score was also negatively impacted by memory and auditory processing limitations.

By fourth grade, Steve's phonological awareness and phoneme-grapheme knowledge skills had improved, and his reading of nonsense words and spelling scores fell within the normal limits. However, his reading vocabulary, reading comprehension, and written expression scores fell in the below-average range because of persistent language deficits. Steve's performance on the CELF-5 Metalinguistic Test indicated adequate meta-pragmatic skills (social communication skills) and below-average meta-semantic skills (understanding multiple meanings and abstract idioms), suggesting that Steve had good social communication skills but was missing deeper meanings that are being conveyed in conversation.

By 11th grade, Steve's language scores fell within normal limits, with the exception of the TAPS-3 auditory comprehension, auditory reasoning, and memory scores. Steve's foundational language skills were average, and his higher-level language skills fell in the above-average range. Steve continues to have reading comprehension concerns.

■ ■ ■ CASE STUDY

As an 11th grader, Steve's exceptional strengths include his work ethic, determination, desire to be a good student, positivity, and great sense of humor. Beyond being a hard worker in school and a talented athlete, he is very socially aware. He picks up on social cues and nuances. He instinctively gets a sense of those around him and goes out of his way to make sure people feel comfortable. Steve's strong social skills are especially impressive given his longstanding history of speech-language and learning difficulties.

Steve is performing well in school, although reading comprehension continues to be an area of weakness for him, especially if he is not given the opportunity to re-read information to glean deep meaning. Steve continues to struggle with working memory and listening skills; however, he compensates for these limitations by following up with his teachers or friends when he has missed information. His higher-level language skills are excellent. Steve feels confident with his school performance because he is given extended time on tests and in-class assignments. With the accommodation of extended time, he does well on in-class tests. The school psychologist is requesting that Steve be given extended time on standardized tests (e.g., the SAT and ACT) because of his longstanding history of language-based learning difficulties.

TREATMENT, MANAGEMENT, AND INTERVENTION

The identification and support of students with speech and language disorders is a goal of response to intervention (RTI), which is explained in the following section. This is followed by descriptions of evidence-based practice interventions for SSDs and SLDs.

Response to Intervention

An RTI is a multi-tiered approach to the early identification and support of students with learning and behavior needs. It also considers how well children respond to intervention for a variety of disabilities that impact their school performance (see Chapter 20).

Speech and language disorders may impede learning due to impairments in both spoken and written language. Components of RTI include universal screening, high-quality instruction, interventions matched to student need, frequent monitoring of progress, and use of a data-based approach to making educational decisions (see Chapter 33). SLPs assist in the implementation of RTI through direct screening, assessment and treatment, collaboration with team members, and consultation with classroom teachers to provide support for children with communication disorders.

The SLP may function in a consultant role to parents, classroom teachers, and speech-language pathology assistants. In this role, the SLP conducts the assessment, designs the intervention, and supervises its implementation. The SLP may conduct individual or group therapy outside of the classroom or choose direct intervention within the classroom setting creating a more natural and functional communication environment. In other models, the SLP works collaboratively with other therapists such as occupational and physical therapists to optimize communication in daily living. Therapy should actively involve the child, follow the child's lead when possible, and take into account the culture of the child's family.

Intervention for Speech Sound Disorders

Children with SSDs may require a motor-based intervention approach if the disorder is thought to be articulatory based or a linguistic phonological approach if the disorder is hypothesized to result from inadequate knowledge of the sound system. Often a combination of both approaches is employed. In a motor-based approach to intervention, the child is first taught to discriminate and contrast the sounds in error. For example, if a child has the /k/ sound in error, pictures of a cat and bat may be presented. The child is asked to point to the picture that starts with the /k/ sound. Next, the target sounds are taught in isolation followed by single syllables, words, phrases, and sentences. The ultimate goal is to produce target sounds correctly in conversational speech. In a phonological-based approach, the goal is to teach phonological rules, sound contrasts, and phonological patterns of the language. For example, if a child deletes the final consonant sounds in words, he or she is presented with the syllable /ka/ and is asked to add the /t/ on the end of the word. Other sounds such as /p/, /b/, and /n/ may be added to the end of /ka/ to produce the words *cap*, *cab*, and *can*. In the phonological approach, the goal is to generalize the final consonant rule across multiple words.

A child with a more severe SSD, such as CAS, requires intensive and early intervention. A motor programming–based approach is essential because the core feature of CAS is difficulty with the motor planning aspects of speech production (Strand, 2017). Motor programming approaches utilize motor-learning principles, including the need for many repetitions of speech movements to help the child acquire skills and to accurately, consistently, and automatically make sounds and sequences of sounds. Remediation of CAS should progress systematically through hierarchies of task difficulty.

Other important recommendations for therapy for SSD include 1) stressing sequences of movements, 2) using repetitions of drill-oriented sessions, 3) considering auditory discrimination training, 4) emphasizing self-monitoring, 5) providing multiple modality input, 6) manipulating prosodic features, 7) employing compensatory strategies, and 8) providing successful experiences (Strand, McCauley, Wiegand, Stoekel, & Baas, 2013).

Intervention for Spoken Language Disorders

Children with SLDs may require intervention for social language skills, vocabulary, and grammar. Children with social language deficits, such as ASD, may demonstrate limitations in their use of language. They may lack a variety of pragmatic language skills, including presupposition (social knowledge of the listener's perspective, also known as theory of mind; see Chapter 18), referential skills (identifying for the listener what content the speaker is referring to), staying on topic, taking conversational turns, and recognizing and repairing conversational breakdowns. Therapists often use social stories that describe a situation that the child encounters in daily living to model appropriate social language skills.

Children with SLD may exhibit deficits in vocabulary, which may also impact written language, as proficient readers have strong vocabularies. Vocabulary should be taught employing a developmental sequence. For example, early quantitative words are *one*, *many*, *much*, *some*, and *more*. Later acquired quantitative words are *few*, *couple*, *nearly*, and *almost*. Qualitative words should be taught in pairs such as *big/little*, *tall/short*, *hot/cold*, and *wide/narrow*. Spatial and temporal terms may include *in*, *on*, *at*, *by*, *in front*, *behind*, *before*, *after*, *first*, and *last*. Early conjunctions are *and*, *but*, *because*, *when*, *or*, *if*, *although*, and *unless*.

Older students with SLD may have difficulty with multiple meanings for words, idioms, and figurative

language such as metaphors and similes. Some children may present with word-retrieval difficulties and word-finding difficulties due to a lack of established representation in the child's **lexicon** (vocabulary) or poor word retrieval. Intervention should focus on organization of the child's lexicon and generalization to everyday use. Games can be used to teach categorization of common items such as food or animals.

Many children with SLD have difficulty with morphology and syntax. Intervention for these deficits should follow a developmental sequence. Morphological interventions seek to establish awareness of syllables and sounds, identify roots and affixes, and understand relationships with other words. Syntactic interventions may focus on pronouns, plurals, and verb tenses. In older children and adolescents, therapy includes increasing the complexity of the individual's spoken and often written language by elaboration of noun phrases, adverbial phrases, and embedded sentences.

OUTCOMES

Children with early childhood histories of SSD and SLD present with differing longitudinal trajectories of speech, language, literacy, and academic skills. Previous studies have identified risk factors for poor outcomes for individuals with SSD, including male gender, comorbid disorders, persistent speech sound errors, lower nonverbal cognitive abilities, motor impairment, maternal education, and social disadvantage (Harrison & McLeod, 2010; Lewis et al., 2015; Wren et al., 2016). A family history of speech, language, and learning disorders confers additional risk for poor outcomes. Children whose SSD and SLD resolve before adolescence tend to have better outcomes than those whose disorders persist into school age and adolescence.

SLDs may persist into adolescence and adulthood. For many children, their SLDs may resolve by early elementary school; however, the individual may continue to experience difficulty with written language (see Chapter 20). The development of written language relies on the language base established with the acquisition of spoken language, and draws on phonological awareness skills, vocabulary, morphology, and syntax shared with spoken language (See Figure 17.1). Children with SLD are at risk for literacy difficulties due to poor oral language and narrative abilities, phonological awareness, and vocabulary. They demonstrate difficulty with alphabetic knowledge, phoneme-grapheme correspondences, spelling and orthographic knowledge, and word awareness (see Chapter 20).

Although spoken language lays the foundation for written language, they differ in significant ways. For example, literacy is more formal and must be explicitly taught to children, whereas spoken language emerges effortlessly for most children. Literacy utilizes different perceptual and cognitive processes. In written language, vocabulary and sentence construction is more explicit to allow for complex connections among ideas, and the focus is on a central topic with a predictable organization of ideas. Children with early childhood SLDs should be monitored for literacy development. The interaction among the severity of the disorder, comorbid conditions, and early and appropriate interventions impacts the long-term educational, occupational, and social-emotional outcomes for the individual.

SUMMARY

- Children with speech and language disorders comprise a heterogeneous group with different profiles of deficits.
- The SLP's scope of practice includes screening, assessment, diagnosis, and treatment of speech, language, and learning disorders.
- The etiological basis for a disorder is critical in identifying profiles of deficits and strengths.
- Tailored interventions should be designed for specific speech, language, and learning profiles.
- Comorbid conditions may impact long-term outcomes for children with speech, language, or learning disorders.

CHAPTER 18

Autism Spectrum Disorder

Deborah Potvin and Allison B. Ratto

Upon completion of this chapter, the reader will

- Be familiar with the core features of autism spectrum disorder
- Understand the importance and process of screening, early identification, and intervention for autism
- Be able to identify the conditions associated with autism spectrum disorder
- Be familiar with the developmental course and outcomes

Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by persistent impairments in reciprocal social communication and social interactions and restricted, repetitive patterns of behavior, interest, or activities. These core diagnostic features are present from an early age and significantly impact daily functioning; however, the manifestation of these symptoms and their impact vary based on the nature and severity of the autistic features; chronological age; temperament; and the individual's level of intellectual, language, and adaptive functioning.

This heterogeneity complicates the diagnosis and treatment of individuals with autism. In addition, autism is often seen in the context of comorbid medical and behavioral conditions, which can cloud diagnosis and change prognosis and treatment needs. Despite these challenges, evidence of the effectiveness of early and intensive intervention in improving adaptive, intellectual, and language function in young children with autism (Hampton & Kaiser, 2016; Reichow, 2012) lends urgency to the need for effective diagnosis. See

the textbox titled A Note about Language for a brief discussion of the language used in this chapter.

■ ■ ■ CASE STUDY

Diego is a 4-year-old boy with a history of language delay who is having behavioral difficulties at home and school. As an infant, he was irritable and difficult to soothe. He started speaking some Spanish words at around 12 months of age, but by 24 months, he still spoke only a few single words and no phrases. Although his parents were told this was because he was learning two languages, Diego's older sister did not have this same problem. His parents sought out early intervention services for him, and Diego was identified as having a language delay. With speech therapy, he began making progress and now, at age 4, is speaking in short sentences, primarily in English. His language tends to be somewhat repetitive, and he often uses phrases out of context that he has heard on television. He has learned all of his letters and numbers, and he often surprises his

A NOTE ABOUT LANGUAGE

There is debate about the value of person-first versus identity-first language among professionals, self-advocates, and families in the world of autism. Person-first language (i.e., “person with autism spectrum disorder”) is considered standard practice among most professionals, and families often prefer this language as well, arguing that this emphasizes the humanity and dignity of the individual. Self-advocates often prefer identity-first language (i.e., “autistic person”), arguing that a person cannot be separated from his/her autism and that “autistic” should be used in the same way as terms describing culture (e.g., “Muslim woman,” “African American boy”). This chapter utilizes person-first language for consistency with common professional practice and other sections of this text. However, the reader is encouraged to read the Autistic Self-Advocacy Network’s statement on identity-first language for additional perspective (www.autisticadvocacy.org). The terms *autism* and *ASD* are used interchangeably in this chapter as they are in clinical practice.

teachers by reading words aloud. Diego is a friendly, outgoing boy. He often walks up to adults and other children and touches them or tries to hand them a toy even if he has never met them before. He and his younger brother like to play with cars and sometimes act out their favorite movies together. Diego often follows other children around on the playground at school, but he struggles to play cooperatively with them. If other children do not want to play “his way,” Diego often becomes upset and has a tantrum. He gets very upset when he has to have his hair or nails cut, and he covers his ears and hides whenever his mother uses the vacuum cleaner. He sometimes flaps his hands when he is excited or stressed. Diego is rarely able to sit still for more than a few minutes and struggles to pay attention at school. His parents tried giving him a stimulant medication that his pediatrician prescribed, but they stopped the medication after he became very anxious and agitated. His parents and teachers are proud of his early academic skills, but they are worried about his problems participating in classroom activities and getting along with other children.

CASE STUDY

Michael was born at term following an unproblematic pregnancy and delivery. His parents became concerned around the age of 9 months, when he was not babbling like other children his age. He was seen for his first assessment at 12 months, with findings of appropriate gross and fine motor skills and delays in both expressive and receptive language. Following this initial assessment, Michael began receiving early intervention services, including intensive speech and language therapy. At follow-up assessments at 18, 24, and 30 months, Michael showed slow but steady progress with language and, by the age of 2½, was using a few consistent signs. The question of a possible ASD diagnosis was raised by the parents, but Michael’s therapists described him as a happy and social little boy and pointed out that he showed no clear repetitive behaviors. However, at his 36-month assessment, Michael showed

subtle regression in his language skills and had stopped using his signs. Although quite pleasant and calm, he did not engage with the assessment tasks and spent most of the time in repetitive play, including opening and closing the doors and watching toys as he dropped them to the floor. At that time, Michael was diagnosed with an ASD and began intensive **applied behavior analysis (ABA)** therapy. Through therapy, he continued to make gains in adaptive skills (e.g., toileting and classroom routines). He showed little progress with language, and his family decided to introduce an augmentative/alternative communication device at the age of 5. The use of this device was initially focused on allowing Michael to request preferred activities and foods, but, as Michael became more comfortable, it evolved to include everyday routines. At the age of 6, Michael entered first grade in a primary autism classroom, which allowed for ABA-based instruction as well as opportunities to interact with typically developing children in the context of a buddies program.

CASE STUDY

Kay was born prematurely, at 31 weeks’ gestational age, weighing 3 pounds, 5 ounces. Despite her early arrival, she had a fairly uneventful stay in the neonatal intensive care unit and was able to go home after 6 weeks, breathing and eating on her own. Her parents were very aware of the risks for early developmental delays in children born prematurely and monitored Kay’s development carefully. To their delight, she appeared to meet all of her developmental milestones on time.

As a preschooler, however, Kay’s teacher began to express concerns about some of her behaviors. She had a hard time adjusting to any changes in the routine, often becoming upset and quickly spiraling into a full meltdown when there was a minor change to the schedule. She was also a bit slow with some fine motor skills, including cutting and drawing. In addition, around this time, Kay’s parents noted that her play seemed different from the other children. Although she enjoyed pretend play with

her dolls and toy ponies, she tended to repeat the same scenes over and over. She was happy to have her parents play with her if they would stick with the script, but she got upset if other children tried to join her. Because of these concerns, Kay started participating in play therapy and occupational therapy.

As she progressed through elementary school, Kay was eager to make friends and have play dates. However, when other children came over, she typically greeted them enthusiastically but then went off to play on her own. Although the other girls in her class had moved on to different types of play, Kay still preferred to act out scenes with her toy ponies and had expanded that interest to reading every book she could find about horses. Kay was also struggling in school. The meltdowns continued to occur on a regular basis at school and at home had become more intense. In particular, when doing homework Kay needed to have everything “just so” and would become distraught and unable to continue if there was a single mistake or problem that seemed too hard. Although she seemed to have a strong vocabulary and learned to read easily, she had difficulty paying attention during group lessons and had a hard time answering questions about what she had read.

With these ongoing difficulties interfering with her school work and creating a stressful home environment, Kay was referred for a speech and language assessment. Although her core language skills were age appropriate, the speech-language therapist was concerned about her pragmatic or social language and recommended a more comprehensive, neuropsychological assessment. Following this assessment, Kay was finally diagnosed with ASD at the age of 10. In addition to changes in her school program and the introduction of an individualized education program (IEP), Kay began participating in cognitive behavioral therapy (CBT) with a practitioner experienced in working with girls with autism and joined a social skills group, which included cognitive flexibility training.

Thought Questions:

How can medical providers facilitate early diagnosis of ASD? Once a diagnosis is established, what recommendations should families receive about further evaluation and intervention? How can providers prepare families for some of the changes and struggles that occur as children with autism develop? How does autism’s presentation change in the presence of comorbid neurodevelopmental or medical conditions, and how do these comorbid conditions affect diagnosis, intervention, and developmental trajectory? What are the advantages and disadvantages of different educational settings for children with ASD? What measures can be taken to successfully include a child with ASD in a general education setting? When might a more specialized setting be appropriate?

DEFINITIONS, DESCRIPTION, AND CLASSIFICATIONS

There is significant heterogeneity among individuals with ASD. Still, they all share two core domains of symptoms: impairments in social communication and restricted/repetitive patterns of behavior and interest (see diagnostic criteria in Table 18.1).

Persistent Deficits in Social Communication and Interaction

Impairments in social communication and interaction skills are critical to the diagnosis of ASD. The American Psychiatric Association’s *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)* criteria for ASD require that individuals show evidence of core difficulties in three areas: 1) nonverbal communication, 2) social-emotional reciprocity, and 3) social relationships (APA, 2013). There must be evidence that these difficulties began in early development, though the *DSM-5* acknowledges that some individuals, particularly those with higher cognitive and intellectual abilities, may not show functional impairment from these challenges until later ages, as social demands increase and become more subtle and complex (see the Previous Diagnostic Categories textbox).

Impairments in **nonverbal communication** are among those most classically associated with ASD. Individuals with ASD commonly have difficulty in making eye contact and fluidly coordinating eye gaze with other communicative behaviors. Impaired eye gaze is one of the earliest and most consistent signs of ASD, emerging as early as the first year of life (Baranek, 1999; Clifford et al., 2007). Eye-tracking studies have found that individuals with ASD spend less time looking at people’s eyes and more time focused on objects and, when looking to faces, more time fixated on the mouth (Chawarska, Macari, & Shic, 2012; Klin, Jones, Schultz, Volkmar, & Cohen, 2002). Impairments in other aspects of nonverbal communication are also common in ASD, including a reduced range of facial expressions, reduced use of gestures, and markedly flat or unusual vocal intonation or **prosody** (patterns of stress and intonation in speech) (Rapin & Dunn, 2003).

Along with problems using nonverbal communication behaviors, individuals with ASD also have difficulty understanding nonverbal communication from others, including problems with accurately interpreting facial expressions, tone of voice, and body language (Dawson, Webb, & McPartland, 2005; Silverman, Bennetto, Campana, & Tanenhaus, 2010). Several studies have also found that attending to faces, which engenders positive emotions in typically developing

Table 18.1. Diagnostic criteria for autism spectrum disorder

- A. Persistent deficits in social communication and social interaction across multiple contexts, as manifested by the following, currently or by history (examples are illustrative, not exhaustive; see text):
1. Deficits in social-emotional reciprocity, ranging, for example, from abnormal social approach and failure of normal back-and-forth conversation; to reduced sharing of interests, emotions, or affect; to failure to initiate or respond to social interactions.
 2. Deficits in nonverbal communicative behaviors used for social interaction, ranging, for example, from poorly integrated verbal and nonverbal communication; to abnormalities in eye contact and body language or deficits in understanding and use of gestures; to a total lack of facial expressions and nonverbal communication.
 3. Deficits in developing, maintaining, and understanding relationships, ranging, for example, from difficulties adjusting behavior to suit various social contexts; to difficulties in sharing imaginative play or in making friends; to absence of interest in peers.

Specify current severity:

Severity is based on social communication impairments and restricted, repetitive patterns of behavior.

- B. Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least two of the following, currently or by history (examples are illustrative, not exhaustive; see text):
1. Stereotyped or repetitive motor movements, use of objects, or speech (e.g., simple motor stereotypes, lining up toys or flipping objects, echolalia, idiosyncratic phrases).
 2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behavior (e.g., extreme distress at small changes, difficulties with transitions, rigid thinking patterns, greeting rituals, need to take same route or eat same food every day).
 3. Highly restricted, fixated interests that are abnormal in intensity or focus (e.g., strong attachment to or preoccupation with unusual objects, excessively circumscribed or perseverative interests).
 4. Hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment (e.g. apparent indifference to pain/temperature, adverse response to specific sounds or textures, excessive smelling or touching of objects, visual fascination with lights or movement).

Specify current severity:

Severity is based on social communication impairments and restricted, repetitive patterns of behavior.

- C. Symptoms must be present in the early developmental period (but may not become fully manifest until social demands exceed limited capacities, or may be masked by learned strategies in later life).
- D. Symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning.
- E. These disturbances are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay. Intellectual disability and autism spectrum disorder frequently co-occur; to make comorbid diagnoses of autism spectrum disorder and intellectual disability, social communication should be below that expected for general developmental level.

Note: Individuals with a well-established DSM-IV diagnosis of autistic disorder, Asperger's disorder, or pervasive developmental disorder not otherwise specified should be given the diagnosis of autism spectrum disorder. Individuals who have marked deficits in social communication, but whose symptoms do not otherwise meet criteria for autism spectrum disorder, should be evaluated for social (pragmatic) communication disorder.

Specify if:

With or without accompanying intellectual impairment

With or without accompanying language impairment

Associated with a known medical or genetic condition or environmental factor

(Coding note: Use additional code to identify the associated medical or genetic condition.)

Associated with another neurodevelopmental, mental, or behavioral disorder

(Coding note: Use additional code[s] to identify the associated neurodevelopmental, mental, or behavioral disorder[s].)

With catatonia (refer to the criteria for catatonia associated with another mental disorder)

(Coding note: Use additional code 293.89 catatonia associated with autism spectrum disorder to indicate the presence of the comorbid catatonia.)

individuals, tends to activate the amygdala and feelings of fear and anxiety in those with ASD.

Although impairments in verbal communication (i.e., language skills) are not required for the diagnosis of ASD, they are nonetheless a common feature of the disorder. Language delay is the most frequent first concern for parents of children later diagnosed with ASD (Chawarska et al., 2007). Although language delay

from infancy is the most common presentation, in about 25%–30% of children with ASD early language development is typical but subsequently plateaus or regresses between 18 and 24 months (Parr et al., 2011; Rogers, 2004). Impairments in core language may persist throughout the lifespan, with an estimated 30% of individuals with autism classified as minimally verbal in adulthood (Tager-Flusberg & Kasari, 2013). These

PREVIOUS DIAGNOSTIC CATEGORIES

In the *DSM-IV-TR* (APA, 2000), ASD was captured under the category of Pervasive Developmental Disorders and individuals could be diagnosed with Autistic Disorder, Asperger's Disorder, or Pervasive Developmental Disorder–Not Otherwise Specified. Studies of differential diagnosis and long-term outcomes did not support distinctions between these diagnoses (particularly between Autistic Disorder and Asperger's Disorder) and found that even when using gold-standard diagnostic procedures, diagnostic categorization was not reliable across sites (Lord et al., 2012a; Witwer & Lecavalier, 2008). These findings drove the decision to move to the single category of Autism Spectrum Disorder in the *DSM-5*, which includes the provision that anyone diagnosed under *DSM-IV-TR* retains his or her diagnosis under *DSM-5*. Providers may still encounter families and individuals who refer to their *DSM-IV-TR* diagnosis. This is particularly true for individuals diagnosed with Asperger syndrome, who often identify more strongly with this label due in part to its more positive associations with intelligence and savant-like skills in the media and society at large.

individuals often communicate through augmentative/alternative communication (AAC) supports, discussed in more detail below.

Among those with intact core language skills, impairments in higher-order language, such as language organization, verbal reasoning, and pragmatic skills, are common (Boucher, 2012). Individuals with ASD may have an impressive vocabulary and strong cognitive abilities but still struggle with understanding idioms, metaphors, sarcasm, and other subtle, nonconcrete features of language. See the Social Communication Disorder textbox for a brief discussion of a new clinical diagnosis introduced in the *DSM-5*.

Impairments in both verbal and nonverbal communication skills contribute to broader difficulties in **social-emotional reciprocity** (i.e., difficulties relating to others). In early childhood, these deficits often manifest through reduced **joint attention**, which is the ability to share a common point of reference, such as a child pointing to an airplane flying overhead and saying "Look!" while pointing and using eye gaze (Mundy & Newell, 2007). Young children with ASD are less likely to initiate joint attention with others and often struggle to respond to others' joint attention bids.

Young children with ASD are also less likely to spontaneously give and show objects to others and often prefer to play alone (Zwaigenbaum, Bryson, & Garon, 2013). As children age, deficits in social-emotional reciprocity are evident through more complex difficulties and as social cognition deficits.

Children and adults on the spectrum commonly struggle to initiate and maintain reciprocal conversations with others (Paul, Orlovski, Marcino, & Volkmar, 2009). They often have difficulty demonstrating interest in others' ideas and experiences and have trouble picking up on subtle conversational cues. Individuals with ASD also commonly struggle with **theory of mind**, which is the ability to intuit and understand others' thoughts, emotions, and perspectives, particularly when they differ from one's own experience (Yirmiya, Erel, Sheked, & Solmonica-Levi, 1998). They may assume that others' experiences are the same as their own or simply be unable to guess what another person is thinking or feeling.

Reduced social-emotional reciprocity in turn leads to difficulties in initiating and maintaining relationships with others, particularly with peers (Travis, Sigman, & Ruskin, 2001). While children with autism

SOCIAL COMMUNICATION DISORDER

The *DSM-5* introduced the new, clinical diagnosis of Social (Pragmatic) Communication Disorder, characterized by "persistent difficulties in the social use of verbal and nonverbal communication" (APA, 2013, p. 47) in children who do not meet diagnostic criteria for ASD. Deficits in social communication are present across a range of neurodevelopmental disabilities and have been shown to be present in children who do not show the restricted, repetitive patterns of behavior, interest, or activities associated with ASD (Bishop & Norbury, 2002), though the variable presentation of restricted, repetitive behaviors between individuals and across the lifespan raises concerns about accurately distinguishing between the two disorders. In addition, further research is needed to understand appropriate assessment techniques and treatments for this new diagnosis (Norbury, 2014).

were historically thought of as being unable to develop attachments to others, including their parents, more recent research has shown that while attachment behaviors may differ, these children generally develop very close bonds with their parents and other individuals important to them (Rutgers, Bakermans-Kranenburg, van Ijzendoorn, & van Berckelaer-Onnes, 2004).

Most consistently, children and adults with ASD struggle with peer relationships (Bauminger & Kasari, 2000; Orsmond, Krauss, & Seltzer, 2004). Some may prefer to be alone and actively avoid playing with peers, while others are highly socially motivated but struggle to make and keep friends due to their social skill deficits. In early and middle childhood, deficits in play skills contribute to difficulty developing peer relationships (Jordan, 2003).

Children with ASD often struggle to develop functional play (using toys as intended) and pretend play (using objects representationally and engaging in “make believe”), and they have trouble playing cooperatively with others (Kasari, Freeman, & Papparella, 2006). Some children learn to engage in pretend play but do so in a highly “scripted” manner, following the same routine each time or being unable to incorporate others’ ideas into play.

As these children age and move into adolescence and adulthood, the overwhelming majority express an interest in dating and sexual activity but are less likely than their non-autistic counterparts to develop romantic relationships, particularly long-term relationships (Byers, Nichols, & Voyer, 2013; Strunz et al., 2017). Of note, rates of same-sex attraction, attraction to both sexes, and gender nonconforming feelings are significantly higher in adults with ASD, and this may further complicate their romantic relationships (Dewinter, De Graaf, & Begeer, 2017).

Restricted/Repetitive Patterns of Behavior, Interest, and Activities

Although differences in social “give and take” are considered central to the diagnosis of autism, **restricted/repetitive behaviors and interests** (RRBIs) are often the most visible symptoms (Leekam, Prior, & Uljarevic, 2011). Strict adherence to routines is common among people with ASD. This can extend to food selectivity, rituals related to daily routines, and difficulties with transitions and changes in their usual environments. For example, having a substitute teacher for the day or needing to take a different route to school may be extremely distressing for a child with ASD. Repetitive motor mannerisms, such as hand flapping or intense spinning, may also be observed, as well as repetitive use of objects, such as lining things up or becoming

intensely focused on the parts of an object (e.g., repetitively spinning wheels on a toy car). Young children with autism may have attachments to unusual items rather than to soft or cuddly toys.

Repetitive, stereotyped, and idiosyncratic language is also a common feature of ASD. Individuals may engage in immediate **echolalia** (repeating others’ speech) or use delayed echolalia or “scripting,” in which they parrot previously heard phrases or sentences (Rapin & Dunn, 2003). Individuals with ASD may also speak in an overly formal manner, with younger children sometimes described as speaking like “little professors.”

Unusual responses to sensory input are commonly reported as well (Marco, Hinkley, Hill, & Nagarajan, 2011). These may include insensitivity to some inputs, such as pain or temperature, or overreactions to other inputs, such as noises, touch, or odors. For example, a child may cover his or her ears and scream in response to certain sounds, such as a vacuum cleaner or blender, or refuse to have his or her nails cut or hair trimmed. The same child may also actively seek out other sensory experiences by staring out of the corners of their eyes, sniffing objects without a clear scent, or stroking surfaces or textures.

Restricted interests are also a common feature of autism. Individuals may develop intense interests in and knowledge of highly specific topics. These topics may be unusual (e.g., vacuum cleaners or road signs), or they may be common interests that are pursued with uncommon intensity (e.g., trains or *Star Wars*). Restricted/repetitive behaviors and interests often change in their presentation, focus, and intensity over the lifespan. These symptoms can significantly impair an individual’s daily functioning and impede social interactions, but they do not necessarily do so. Behaviors that are present but not impairing (e.g., hand-flapping or intense interest in flags) do not need to be directly targeted for treatment. It is also worth noting that many self-advocates with ASD have pointed out the potential benefits of restricted/repetitive behaviors and interests. For example, an intense interest may help an individual to identify a career path or develop friendships around shared interests. Likewise, although strict adherence to routines may interfere with functioning, it may also reduce anxiety by ensuring that an individual knows what to expect.

Specifiers and Severity Levels

In recognition of the removal of separate diagnostic categories and use of the single label “ASD” for all individuals, the *DSM-5* provides a number of specifiers for clinicians to use; clinicians should identify whether or not the individual has a co-occurring intellectual

Table 18.2. Severity levels for autism spectrum disorder

Severity level	Social communication	Restricted, repetitive behaviors
Level 3 "Requiring very substantial support"	Severe deficits in verbal and nonverbal social communication skills cause severe impairments in functioning, very limited initiation of social interactions, and minimal response to social overtures from others. For example, a person with few words of intelligible speech who rarely initiates interaction and, when he or she does, makes unusual approaches to meet needs only and responds to only very direct social approaches.	Inflexibility of behavior, extreme difficulty coping with change, or other restricted/repetitive behaviors markedly interfere with functioning in all spheres. Great distress/difficulty changing focus or action.
Level 2 "Requiring substantial support"	Marked deficits in verbal and nonverbal social communication skills; social impairments apparent even with supports in place; limited initiation of social interactions; and reduced or abnormal responses to social overtures from others. For example, a person who speaks simple sentences, whose interaction is limited to narrow special interests, and who has markedly odd nonverbal communication.	Inflexibility of behavior, difficulty coping with change, or other restricted/repetitive behaviors appear frequently enough to be obvious to the casual observer and interfere with functioning in a variety of contexts. Distress and/or difficulty changing focus or action.
Level 1 "Requiring support"	Without supports in place, deficits in social communication cause noticeable impairments. Difficulty initiating social interactions and clear examples of atypical or unsuccessful responses to social overtures of others. May appear to have decreased interest in social interactions. For example, a person who is able to speak in full sentences and engages in communication but whose to-and-fro conversation with others fails and whose attempts to make friends are odd and typically unsuccessful.	Inflexibility of behavior causes significant interference with functioning in one or more contexts. Difficulty switching between activities. Problems of organization and planning hamper independence.

impairment, language impairment, or catatonia and whether the ASD is conceptualized as occurring secondary to a known medical, genetic, or environmental factor or to another neurodevelopmental, mental health, or behavioral condition. Clinicians are also encouraged to specify the severity of the condition using one of three severity levels (Table 18.2), which are determined based on the level of impairment in social communication and restricted/repetitive behaviors. There has been very limited research on these severity levels. Thus far, findings have emphasized that there is a considerable degree of heterogeneity in ASD severity and that impairments in social communication, restricted/repetitive behaviors, adaptive behavior, and intellectual ability are often discrepant with one another within individuals (Mehling & Tassé, 2016; Weitlauf, Gotham, Vehorn, & Warren, 2014). Research on the stability of the *DSM-5* severity levels over time has not yet been performed; however, given the variability of developmental trajectories in ASD, it is expected severity levels may change over the lifespan.

Strengths of the Autism Spectrum

In addition to the challenges experienced by individuals with autism, it should also be noted that there are several strengths associated with this condition. Individuals with ASD may have an exceptional memory, an excellent eye for detail, advanced visual-spatial skills,

and strong abilities for logical and hierarchical reasoning (De Martino, Harrison, Knafo, Bird, & Dolan, 2008; Happé & Frith, 2006; Narzisi, Muratori, Calderoni, Fabbro, & Urgesi, 2013). For this reason, autistic traits have been commonly found in professionals working in math, computer science, and other sciences; adults on the spectrum may be particularly likely to excel in these fields (Baron-Cohen, Wheelwright, Skinner, Martin, & Clubley, 2001).

DEVELOPMENTAL COURSE OF AUTISM SPECTRUM DISORDER

As a neurodevelopmental disorder, autism is a condition that grows and changes with the child (see Table 18.3). Some symptoms may begin to emerge in the first year of life, though these are not commonly noted other than in severe cases or by parents with a family history (e.g., an older child) with ASD. Parents may describe an infant as being very difficult to soothe or as being quite content to be left alone. They may begin to notice that the infant is less likely to make eye contact or babbles less frequently than other children of the same age.

Symptoms of ASD are most often first observed in the second year of life (between 12–24 months of age). By far, the most common symptom parents report as their initial concern is a delay in language skills,

Table 18.3. Prominent symptoms and challenges by age

Birth–12 Months	12–24 Months	2–5 Years	Middle Childhood	Adolescence	Adulthood
Reduced eye contact and gaze to faces	Language delays	Reduced peer interactions	Deficits in reciprocal conversation	Problems with executive functioning	Under-employment
Lack of social smile	Lack of gestures	Unusual or stereotyped language	Poor friendship quality	Poor understanding of social cues	Housing challenges
Reduced babbling and vocalizations	Poor joint attention	Deficits in pretend play	Problems with attention and learning	Poor hygiene and self-care	Difficulties with activities of daily living
Unusual sensory responses	Repetitive play and behaviors	Unusual and restricted interests		Social isolation and bullying	Few and poor quality relationships
Impaired motor coordination	No response to name	Insistence on sameness			
	Possible developmental regression				

including acquisition of first words and phrases. Many children with ASD do not point or wave hello or goodbye. Children may be described as preferring to play alone and often do not try to engage their parents' interest (for example, by bringing items to them), in contrast to typically developing children who frequently seek parental attention. Parents may also notice unusual play at this age, such as spending a significant amount of time lining up or banging objects and failing to engage in early functional and symbolic play (e.g., pretending to talk on a toy phone or feeding or rocking a baby doll).

In the preschool period, problems playing with other children often become central—they may actively resist playing with peers or may only be willing to play with others if they play according to the child's rules. They may engage in very little pretend play or only do so by carefully reenacting favorite movies or television shows. Children at this age may be easily overwhelmed by transitions and upset by changes in routine or new experiences. Preschool teachers often describe a child who has frequent tantrums, struggles to participate in group activities, and has strong preferences for repeating the same activities over and over.

Most children with ASD are diagnosed by the time they exit the preschool period (CDC, 2018). Some children, however, particularly those who have strong intellectual and language abilities or who have known medical or genetic conditions (e.g., epilepsy) may be diagnosed later (Clarke et al., 2005). During the middle childhood years (elementary and early middle school), problems with attention and academic skills may be most prominent. Difficulties with writing and reading comprehension are common, given the demands for language and executive functioning involved in these tasks. Children who were able to play with peers in the preschool period may begin to struggle more with friendships at this age as the social interactions become

more complex. They may be teased or bullied by other children for their social differences. Children who continue to have meltdowns or tantrums may need well-structured behavioral supports in place, particularly in the school setting.

As children enter puberty and adolescence, the risk for developing comorbid conditions, such as anxiety and depression, increases as they become more aware of their differences and feel increasingly separate from their peers. Problems navigating romantic relationships and sexual feelings may also emerge. Very intelligent children who performed well on the more rote academics of elementary school may have more difficulties in middle and high school. The transition to adulthood is often difficult. Individuals may struggle to be successful in postsecondary education or in work settings, often due to problems with social skills and executive functioning rather than an inability to perform the key tasks. Underachievement and under-employment, a lack of daytime activities, and reduced ability to live independently are common.

PREVALENCE AND EPIDEMIOLOGY

The Centers for Disease Control and Prevention (CDC)'s most recent study—from 2018—reported the prevalence of ASD as approximately 1 in 59 children in the United States. Other countries have reported similar rates, with some variations by ascertainment method and local awareness of autism (Baron-Cohen et al., 2009; Elsabbagh et al., 2012; Kim et al., 2011). There has been a consistent and significant increase in diagnostic rates over time throughout the world. Although researchers are still investigating the factors contributing to this increase, there is mounting evidence that the observed change in prevalence is due largely to increasing awareness of ASD and changes in diagnostic practices over time, such that many children, particularly those from

minority populations, who would have previously gone undiagnosed or been diagnosed with another condition (e.g., attention-deficit/hyperactivity disorder, intellectual disability) are now being identified as having ASD (Coo et al., 2008; Hertz-Picciotto & Delwiche, 2009). The autism spectrum has also expanded over time to include an increasing number of individuals without co-occurring intellectual disability. Fifteen to twenty years ago, approximately 70% of children with autism were classified as intellectually disabled (Fombonne, 2003); more recent studies have found that only 31% of children with ASD also have intellectual disability (CDC, 2018).

Prevalence rates of ASD are affected by a number of demographic factors, including gender, race/ethnicity, and family income. Autism has always been identified in females at a substantially lower rate than in males, with most epidemiological studies reporting an approximately male-to-female ratio of 4 to 1 (Fombonne, 2009). However, a recent meta-analysis of epidemiological studies found that the true ratio is likely closer to 3 to 1, with findings suggesting that females with ASD are more likely to be undiagnosed (Loomes, Hull, & Mandy, 2017). It is also well established that the sex imbalance in prevalence varies with cognitive ability; among individuals with co-occurring intellectual disability, a smaller male-to-female ratio of approximately 2 to 1 exists, while a much larger ratio of as much as 6 to 1 occurs among those with average to above average IQ (Fombonne, 2009; Kirkovski, Enticott, & Fitzgerald, 2013).

Many in the field have described a female protective effect (e.g., Robinson, Lichtenstein, Anckarsater, Happé, & Ronald, 2013), by which female sex directly reduces the risk of autism, and there is evidence that there may be a higher genetic threshold for autism in females (Gilman et al., 2011; Jacquemont et al., 2014; Robinson et al., 2013). However, it has also been hypothesized that ASD may be “camouflaged” in females and that current diagnostic procedures may be biased against females, particularly those without co-occurring intellectual disability (Kirkovski et al., 2013; Lai et al., 2016).

Females have been found to have significant delays in receiving an autism diagnosis relative to males (Begeer et al., 2013; Shattuck et al., 2009; Siklos & Kerns, 2007). This may be due in part to relative social strengths among females on the spectrum, who may show more developmentally appropriate vocabulary and core language skills (Halladay et al., 2015; Hiller et al., 2016), more intact play and imitation skills (Knickmeyer, Wheelwright, & Baron-Cohen, 2008), and greater concerns with being liked by peers (Hiller et al., 2016; Kirkovski et al., 2013). In addition, some

authors have noted that the lower rate of restricted/repetitive behaviors and interests among females relative to males on the spectrum (Mandy et al., 2012; Van Wijngaarden-Cremers et al., 2014) may actually be driven in part by clinician bias, as females may have restricted interests in more “normative” content areas (e.g., books, celebrities, and animals; Halladay et al., 2015; Kirkovski et al., 2013).

Of note, gender identity also likely plays an important role in the manifestations of ASD. Individuals with ASD are significantly more likely to endorse gender nonconforming feelings and behaviors (Strang et al., 2014). Rates of ASD and autistic traits are also significantly elevated among individuals presenting for treatment of gender dysphoria (de Vries, Noens, Cohen-Kettenis, van Berckelaer-Onnes, & Doreleijers, 2010; Edwards-Leeper & Spack, 2012).

Prevalence rates also vary by race/ethnicity. Data from the CDC prevalence studies have consistently found lower rates of diagnosis among Black, Latino, and Asian American children (CDC, 2007, 2012, 2016, 2018). Ethnic minority children also tend to be diagnosed later than their white peers (Liptak et al., 2008; Mandell, Novak, & Zubritsky, 2005; Pedersen et al., 2012). Perhaps due in part to these delays in diagnosis, ethnic minority children have also been reported to have more severe forms of ASD and higher rates of co-occurring intellectual disability than white children (Jarquin, Wiggins, Schieve, & Naarden-Braun, 2011; Liptak et al., 2008), even within samples controlled for socioeconomic status (Mandell et al., 2005; Tek & Landa, 2012).

Economic disparities continue to have a significant effect on access to care among families in the United States (Mandell et al., 2009; see Chapter 42). ASD was initially conceptualized as a disorder of the wealthy; it was believed that highly educated, wealthy parents were more likely to engage in “cold” parenting styles that engendered autistic symptoms in their children as opposed to the warmer, more nurturing parenting styles of low- to middle-income parents (Bettelheim, 1967; Sanua, 1984). Subsequent studies demonstrated that differences in diagnostic rates could be accounted for by biased recruitment in research samples (Schopler, Andrews, & Strupp, 1979; Wing, 1980). However, more recent studies continue to find that low-income children in the United States are less likely to be diagnosed with ASD and tend to be diagnosed significantly later than their middle-income and high-income peers (Durkin et al., 2010; Liptak et al., 2008; Mandell et al., 2005). Although the reasons for this discrepancy are not fully understood, it is suspected to be largely driven by disparities in access to health care and educational supports and knowledge of developmental milestones and disorders.

ETIOLOGY: CAUSES OF AUTISM SPECTRUM DISORDER

ASD has multiple etiologies, with the weight of research pointing to a strong genetic component, while ongoing studies continue to investigate the influence of environmental factors. However, even as our understanding of the etiology of autism expands, for most individuals the cause of an autism diagnosis remains unknown. What is fairly clear is that, with the exception of a minority of children with a perinatal or neonatal neurodevelopmental insult (Lindquest, Carlsson, Persson, & Uvebrant, 2006), ASD is a condition that is present from birth, with infants who go on to develop ASD showing subtle motor delays within the first year of life, well before the emergence of early language and social differences (Bhat, Galloway, & Landa, 2012).

The Genetics of Autism

Research shows strong evidence for a genetic etiology in ASD. The risk of autism in a younger sibling of a child with autism has been found to be as high as 18.7% (Ozonoff et al., 2011), lending weight to the importance of parent education of children with autism and careful monitoring of their younger siblings. Likewise, twin studies have shown a strong concordance (e.g., both twins having ASD) for identical twins (76%), with lower rates for same-sex fraternal twins (34%; Frazier et al., 2014). Although some of these studies point to the interplay between genetics and a shared intrauterine environment in the development of ASD (Hallmayer et al., 2011), others suggest linear inheritance with very little environmental influence (Sandin et al., 2017; Tick, Bolton, Happe, Rutter, & Rijdsdijk, 2016).

Despite strong evidence for the role of genetics in ASD, there is not yet a clear genetic pathway to explain ASD, with most research pointing to multiple pathways. A minority of ASD cases are associated with genetic disorders that have known etiologies (see Table 18.4). Historically, several genetic disorders, including Prader-Willi syndrome, Angelman syndrome, tuberous sclerosis complex, and fragile X syndrome (see Appendix B, Chapter 1, and Chapter 15), have been associated with higher rates of autism, although even in these syndromes the majority of affected individuals do not meet criteria for autism.

With the increasing prevalence of genetic testing through chromosomal microarray (CMA; see Chapter 1), knowledge of the breadth of genetic syndromes associated with autism has expanded. Recent large-scales studies suggest that between 5%–9% of individuals with autism who complete chromosomal microarray analysis have clinically significant or

pathogenic findings (Ho et al., 2016; McGrew, Peters, Crittendon, & Veenstra-VanderWeele, 2012; Tammimies et al., 2015). In addition, approximately 25% of individuals are found to have gene variants of uncertain significance (Ho et al., 2016). However, these findings still reflect the lack of a clear genetic etiology in many individuals with autism, supporting the importance of research on the role of polygenic inheritance, copy number variants, and high numbers of common genetic variants in the genetics of autism (see Chapter 1).

Environmental Factors

It may be that environmental factors interact with genes to cause the symptoms of ASD. The sections that follow describe the evidence, or lack thereof, for associations of obstetric complications, neurodevelopmental insults, intrauterine exposure, prenatal infections, and toxic environmental exposure with ASD.

Obstetric Complications Neither large epidemiological studies nor meta-analyses have strongly associated particular prenatal, perinatal, or neonatal complications with the development of ASD. However, obstetric optimality scores, which reflect the overall health of the pregnancy, delivery, and newborn period, are lower in children subsequently diagnosed with ASD (Dodds et al., 2011; Lyall et al., 2012), and meta-analyses show higher rates of complications during pregnancies of children born with ASD (Gardener, Spiegelman, & Buka, 2009). The causal direction of these findings is unclear, including whether factors that predispose a child to ASD also compromise fetal well-being or whether subtle compromises in fetal well-being increase susceptibility to ASD.

Neurodevelopmental Insults Researchers and clinicians are increasingly recognizing the elevated risk of autism in medically complex children whose medical history is linked with early neurodevelopmental insults. Studies have consistently linked premature birth with an increased risk for ASD. More focused investigations have shown a strong association between extreme prematurity (< 26 weeks' gestation) and ASD, with some estimates indicating that up to 8% of children with a history of extreme prematurity meet criteria for ASD (Johnson et al., 2010). Clinically, children born prematurely may present with a subtle and qualitatively different presentation of autism characteristics than seen in other children with ASD.

Clinicians are also becoming more aware of an increased risk of ASD in children with other medical conditions associated with early neurodevelopmental

Table 18.4. Genetic disorders associated with autism

Genetic disorder	Genetic defect	Primary features	Prevalence of autism
Rett's syndrome	Mutations in the <i>MeCP2</i> gene	Global regression following 6-18 months of typical development; intellectual disability; loss of purposeful hand movements	61% ^a
Cohen's syndrome	Mutations in <i>COH1</i> gene on 8q22	Developmental delay; intellectual disability; microcephaly; hypotonia	54%
Cornelia de Lange syndrome	Mutations in <i>NIPBL</i> , <i>SMC1A</i> , <i>HDAC8</i> , <i>RAD21</i> , and/or <i>SMC3</i> gene	Slow growth; moderate to severe intellectual disability; bone abnormalities	43%
Tuberous Sclerosis complex	Mutations in <i>TSC1</i> or <i>TSC2</i> gene	Numerous benign tumors; intellectual disability; behavioral difficulties; seizures	36%
Angelman syndrome	Mutation in <i>UBE3A</i> gene	Developmental delay; intellectual disability; severe speech impairment; ataxia; seizures; microcephaly	34%
CHARGE syndrome	Mutation in <i>CHD7</i> gene	Multiple physical and neurological abnormalities; delays in motor development	30%
Fragile X syndrome	Mutation in the <i>FMR1</i> gene on the X chromosome	Mild to moderate intellectual disability in males, with higher intellectual functioning in females; behaviors difficulties; seizures	30% ^b ; 22% ^c
Neurofibromatosis type 1 (NF1)	Mutations in the <i>NF1</i> gene	Skin discoloration and tumors along nerves in skin, brain, and other areas; typical intellectual functioning; ADHD; learning disabilities	18%
Down syndrome	Trisomy 21	Mild to moderate intellectual disability; hypotonia; characteristic facial features	16%
Noonan's syndrome	Mutations in <i>PTPN11</i> , <i>SOS1</i> , or <i>RIT1</i> gene	Characteristic facial features; slow growth; heart defects, bleeding problems; range of intellectual functioning	15%
William's syndrome	Deletion of material from chromosome 7	Characteristic facial features; heart defects; mild to moderate intellectual disability; hypersocial personality	12%
22q11.2 deletion syndrome	Deletion on 22q11.2, with implications for <i>COMT</i> and <i>TBX1</i> genes	Characteristic facial features; heart defects; cleft palate; risk for developing schizophrenia and bipolar disorder; developmental delays; ADHD; learning disabilities	11%

^afemales only; ^bmales only; ^cmixed sex

insults. For instance, children with hydrocephalus and cerebral palsy (Lindquest et al., 2006) and congenital heart disease (reviewed in Cassidy et al., 2017) have been found to be at higher risk for ASD. Although the interplay between the neurological insults related to these disorders and the possible underlying genetic factors remains unclear, these findings highlight the need for consistent developmental screenings for these children, with a caution against attributing or “writing off” early developmental concerns to a child’s medical history and not pursuing appropriate interventions.

Intrauterine Exposure Substances that result in an increased risk of birth defects in the developing fetus are termed teratogens (see Chapter 6). These include maternal medications, drugs of abuse, chemicals, and radiation. Past investigations of teratogens tended to focus on substances associated with an

increased risk of congenital malformations and perinatal complications; however, increasing recognition is now being given to the neurobehavioral effects of these substances (Gentile, 2010). For example, thalidomide, a medication used to treat nausea in pregnant women in the early 1960s, was associated with limb deformities in the exposed fetuses. Many years later, adults who had been exposed to thalidomide *in utero* were also found to have higher rates of ASD (Ström-land, Nordin, Miller, Akerström, & Gillberg, 1994). More recently, increased rates of ASD have been found in children exposed in utero to valproic acid, an anti-seizure medication (Christensen et al., 2013). Findings on prenatal exposure to antidepressants have been mixed, with more recent studies suggesting that previously found associations might be better explained by the underlying maternal mood disorder (Brown et al., 2017).

Prenatal Infections Prenatal infection with rubella increases the risk for cerebral palsy, intellectual disability, visual impairments, and ASD depending on the timing of the infection (Chess, 1971). Fortunately, the measles, mumps, and rubella (MMR) vaccination-based immunity in women has all but eliminated this cause of ASD in the United States. Although not as pronounced, an increased risk for autism has also been associated with children with congenital cytomegalovirus. Other viruses and bacteria that commonly infect pregnant women are not specifically associated with a higher risk of ASD in their children. However, a mother's own immune response to infections might cause subtle brain differences in the fetus that could predispose a child to ASD. Large epidemiological studies have found a slightly increased risk of ASD in children whose mother had an infection during pregnancy, particularly if the infection was diagnosed during an inpatient stay—and thus was suspected to be more severe (Jiang et al., 2016; Zerbo et al., 2015).

Toxic Environmental Exposure No known environmental or chemical exposures have been associated with an increased risk for ASD. Toxic exposure has been investigated through studies of air quality, heavy metal exposure, and exposure to endocrine-disrupting chemicals (e.g., PCBs, see Chapter 2). However, much of this research has been hampered by poor or limited designs (Modabbernia, Velthorst, & Reichenberg, 2017). The effect of exposure to mothers and infants, as well as the effect on brain development, needs to be explored in a more systematic way.

Vaccines

Extensive research has found no evidence of a causal link between vaccines and ASD. However, despite the weight of this research, concerns about vaccines and ASD continue to contribute to lower vaccination rates, particularly among younger siblings of children with ASD (Glickman, Harrison, & Dobkins, 2017). Thus, in light of these continued concerns and recent outbreaks of illness that may be prevented by vaccines, therapists and providers should be able to discuss this topic clearly with families.

Since the initial allegation of an association of the MMR vaccine with developmental regression and ASD, a large body of evidence has been published that has refuted the connection. The journal that published the article retracted the publication because of improper scientific practices (The Editors of The Lancet, 2010). Population-based studies, in fact, do not demonstrate an increase in the rate of ASD diagnosis

with the introduction of the MMR vaccination (Demiceli, Jefferson, Rivetti, & Price, 2005). Madsen et al. (2002) compared the rate of autism in more than 400,000 children in Denmark who received the MMR vaccine with about 100,000 children who did not get the vaccine. There was no difference in the rate of autism. Likewise, there is no evidence that the body's immune reaction to the vaccines raises the risk of developing ASD (DeStefano, Price, & Weintraub, 2013). Despite this evidence against a connection between vaccination and ASD, there continues to be a decreased rate of immunization by parents concerned about a possible association (Glickman et al., 2017; Leask, Booy, & McIntyre, 2010). Families should be reassured that the immunization schedule advocated by the American Academy of Pediatrics (AAP) is not associated with the development of ASD.

A second hypothesis relates the ethylmercury-based preservative thimerosal (used as a preservative in pediatric vaccines prior to 2001) to symptoms of ASD in genetically susceptible children (Bernard, Enayati, Redwood, Roger, & Binstock, 2001). After removal of thimerosal from vaccines in Denmark, the rate of diagnosis of ASD actually increased (Madsen et al., 2003), although this could be attributed to the broadened diagnostic criteria and increased awareness of ASD in families and providers.

Brain Development and Neural Circuitry

Differences in the neuroanatomy of children with ASD are present from early in development and subtly affect a number of different regions of the brain, suggesting that autistic brains do look and work differently. However, research is still in the process of defining and quantifying that difference.

Development The early overgrowth theory is one of the most prominent theories explaining the dynamic relationship between neurodevelopment and the emergence of ASD symptoms. This theory hypothesizes that genetic predisposition and/or environmental factors contribute to increased cellular proliferation, migration, and differentiation in the developing brain of a young child with autism (Dinstein, Haar, Atsmon, & Schtaerman, 2017). These factors lead to hyperexpansion of the cortical surface between the ages of 6–12 months, followed by a period of overgrowth in total brain volume, between the ages of 12–24 months (Hazlett et al., 2017). The location of early cortical hyperexpansion within the sensory areas and the correspondence of the timing of these neurological changes with the timing of the emergence of early sensory symptoms and characteristic

social deficits raise further questions about the interplay between these neurological changes and the symptoms of ASD. Interestingly, the overgrowth theory has also been traditionally linked with evidence of **macrocephaly** (large heads) and accelerated head growth in children with ASD (Elder, Dawson, Toth, Fein, & Munson, 2008). However, more recent studies have found no difference in head circumference in children with and without ASD (Dinstein et al., 2017; Zwaigenbaum et al., 2014).

Neural Circuitry The heterogeneity of the behavioral presentation of ASD has complicated research into neuroanatomical differences associated with the disorder. Although there is some agreement as to the brain regions involved in the key features of ASD, including social-communication deficits, repetitive behaviors, and executive functioning weaknesses, research into how these brain regions differ in individuals with ASD has led to inconsistent and sometimes contradictory findings. In general, the neural systems associated with autism are thought to include the 1) fronto-temporal and frontal parietal regions, 2) limbic brain regions, 3) fronto-striatal circuitry, and (4) cerebellum (Duerden, Mak-Fan, Taylor, & Roberts, 2012; reviewed in Ecker, 2017; see Chapter 8 for a discussion of brain anatomy). In addition, individuals with autism show reduced connectivity in the neural circuitry associated with these regions, including the social circuitry of the fronto-temporal regions (Pelphrey, Shultz, Hudac, & Vander Wyk, 2011), the circuitry of the fronto-parietal regions (Solomon et al., 2009), and the fronto-striatal circuitry (Shafritz, Dichter, Baranek, & Belger, 2008). The correlation between reduced connectivity within these neural circuits and performance on measures of social cognition, cognitive control, and repetitive behaviors, respectively, supports the development of a neurobiological model of autism.

DIAGNOSIS AND ASSESSMENT

A diagnosis of ASD is most often the result of an extended process that begins with concerns from parents, teachers, pediatricians, or others in the child's life. As noted above, concerns usually begin within the first few years of life but may not emerge until later for children with more intact core cognitive skills. In young children, the first step in this process is screening, most often performed by the child's pediatrician. Delays in language or social engagement or the presence of repetitive behaviors may raise initial concerns. Formal screening tools are often utilized as part of this process; the most commonly

used of these is the Modified Checklist for Autism in Toddlers (M-CHAT; Pandey et al., 2008; Robins, Fein, Barton, & Green, 2001). The M-CHAT is a brief parent questionnaire suitable for screening toddlers in a pediatrician's office. Although sensitive to symptoms of ASD, it is not specific unless the items endorsed by the family are examined further by interview. The M-CHAT authors have subsequently developed an interview used to confirm the screening questionnaire (Pandey et al., 2008). A revised version was recently published, the Modified Checklist for Autism in Toddlers, Revised with Follow-up (M-CHAT-R/F) with improved positive predictive values (Robins et al., 2014). The M-CHAT is made freely available on the authors' web site with both online and hand scoring (see Additional Resources) and has been translated into several languages. Other well-validated screening tools include the First Year Inventory and the Screening Tool for Toddlers and Young Children (Reznick, Baranek, Reavis, Watson, & Crais, 2007; Stone, Coonrod, Turner, & Pozdol, 2004). See Box 18.1 for more on early diagnosis.

Once a child has "failed" an initial screening, he or she is referred to early intervention services, school-based assessment teams, and/or developmental specialists. ASD is most often diagnosed by physicians and psychologists, especially those with specialized training in this diagnosis, such as developmental pediatricians, pediatric neurologists and psychiatrists, clinical psychologists and neuropsychologists, and speech-language pathologists working as part of a multidisciplinary team. Many other professionals who work with these children (including speech-language pathologists, occupational therapists, behavioral analysts, educators, and social workers) make key contributions to the diagnostic process through their insights, observations, and experience. A thorough medical examination should be conducted to rule out underlying medical conditions; this often includes a referral to an audiologist to rule out hearing impairment. The physical examination should also include an examination of the skin, as children with neurocutaneous syndromes (e.g., tuberous sclerosis) are at higher risk for autism.

At minimum, making a diagnosis of ASD requires gathering information from parents and other caregivers about current symptoms and a thorough developmental, medical, and psychiatric history, along with direct observation and evaluation of the child's social communication skills and behavior. The Autism Diagnostic Interview-Revised (Rutter, LeCouteur, & Lord, 2003) is a structured interview that specifically evaluates current and historical symptoms of ASD; however, it is quite lengthy and is most commonly utilized in research. In clinical practice, providers often utilize

BOX 18.1 EVIDENCE-BASED PRACTICE**The Stability of Early Diagnosis**

Evidence of the effectiveness of early and intensive intervention in improving outcomes for young children with autism lends urgency to the need for effective, early diagnosis. However, the intensity and expense of early intervention also comes with concerns about the accuracy of early diagnosis of autism in children under the age of 3. Ozonoff and associates (2015) studied the stability of early diagnosis in a group of children at high risk for developing autism, comparing early diagnosis at 18 or 24 months with a final diagnosis at 36 months. With diagnosis based on 1) Autism Diagnostic Observation Schedule assessment, 2) use of *DSM-IV* clinical criteria, and 3) diagnosis by a licensed clinician, they found a high degree of stability, 93% at 18 months and 82% at 24 months. Most strikingly, early diagnosis was highly specific (99% at 18 months and 95.5% at 24 months), with the majority of children who were diagnosed with autism at 18 or 24 months retaining that diagnosis at 36 months. However, many children who eventually received an autism diagnosis at 36 months were not diagnosed at either 18 or 24 months, suggesting that some children have a period of early development during which autism features slowly emerge.

- Clinical diagnosis of autism can be accurately made before the age of 3 and can allow for implementation of appropriate early intervention.
- Not all children with autism can be diagnosed before the age of 3, reflecting the importance of periodic screening and follow-up for children at risk for autism or with early developmental delays who do not initially meet criteria for an autism diagnosis.

unstructured interviews, along with parent questionnaires, such as the Social Communication Questionnaire (Rutter, Bailey, & Lord, 2003) or the Social Responsiveness Scale–2 (Constantino & Gruber, 2012). Clinicians should observe the child in the office in play interactions and conversation.

The use of the Autism Diagnostic Observation Schedule–2 (ADOS-2; Lord et al., 2012b) has become widespread in both research and clinical practice for direct observation of ASD symptoms. The ADOS-2 is a semistructured assessment of social communication skills that consists of a series of activities adapted based on the child's language and developmental level. It is primarily play based for younger children and is increasingly driven by conversation skills for older children and adolescents/adults.

Although the ADOS-2 is a very valuable tool, it is important to recognize that its results should not be used in isolation to make diagnostic determinations. In addition to parent report and direct evaluation of the child's social communication skills, best practice for the evaluation of ASD includes formal assessment of cognitive abilities, language skills, motor skills, and other psychiatric symptoms, as well as the input of teachers and others familiar with the child. Neuropsychological evaluation can be critical to understanding the profile of many children with autism and making appropriate recommendations (see Chapter 13). The diagnostic assessment of a child

with possible ASD is often best accomplished in the context of a comprehensive, multidisciplinary evaluation of the child's strengths and weaknesses. A team approach to assessment yields not only a diagnosis, but also critical recommendations based on a global view of the child's abilities and challenges. See Box 18.2 for further discussion on the interdisciplinary team that supports evaluation.

Following the diagnosis of ASD, the AAP recommends that all children be referred for genetic testing, including a chromosome microarray (AAP, 2010). Ongoing management and continuing care should occur with a developmental pediatrician, pediatric psychiatrist, pediatric neurologist, or primary care pediatrician who is well versed in the management of children with ASD. The physician can guide families in determining when additional evaluations are needed, accessing treatments, prescribing medications to help with managing co-occurring symptoms, and coordinating with other medical providers and systems of care. Children who show signs of possible seizures or other neurological abnormalities should also be referred to a neurologist. Although additional medical and biological evaluations are often pursued by families, there is no scientific evidence to support measurement of heavy metal levels in hair, blood, or urine; immunologic parameters in blood; stool flora; urine peptides; or yeast metabolites in the urine in children with ASD (Levy & Hyman, 2005). Periodic assessment

BOX 18.2 INTERDISCIPLINARY CARE**The Role of the Psychologist**

A clinical psychologist is a doctoral-level clinician with extensive training and experience in providing comprehensive mental health and behavioral assessment and care for individuals and families. A neuropsychologist is a psychologist with specialized training in the applied science of brain-behavior relationships. In practice, both psychologists and neuropsychologists work extensively with children with autism. Though their roles are often interchangeable, a psychologist may be more likely to provide ongoing treatment/care while a neuropsychologist may be more involved with extensive, periodic assessments, particularly for children with complex medical histories or comorbid diagnoses that impact neurological functioning.

The diagnostic assessment of a child with autism is best accomplished within a multidisciplinary team, and the psychologist or neuropsychologist plays an important role on that team, helping to ensure that the assessment yields both an accurate diagnosis and recommendations for appropriate treatment within the home and school settings. Following the initial diagnosis, the psychologist or neuropsychologist will also play a role in ongoing care and care management. Often families will meet with the psychologist on a regular basis to check in about their children's progress and to discuss any shift or changes that need to be made to the school or therapy programs. Periodic, psychological assessments of cognitive abilities, language skills, motor skills, and other psychiatric symptoms help to monitor a child's progress and guide treatment recommendations, while an extensive neuropsychological assessment, which adds evaluation of attention, learning and memory, and executive functioning, can provide important information for understanding the complex profile of children with autism and guiding educational programming and intervention.

of the child's cognitive, language, motor, and educational skills is strongly recommended throughout the lifespan to evaluate progress, provide updated treatment recommendations, and assist the family in long-term planning and preparation for the transition to adulthood (see Chapter 40).

ASSOCIATED CONDITIONS

Children with ASD often present with a number of comorbid or co-occurring conditions. These comorbid conditions can shape the presentation and functioning of children on the autism spectrum, with specific behavioral phenotypes associated with specific genetic syndromes (Moss & Howlin, 2009). Likewise, the level of adaptive functioning and the number and type of comorbid psychiatric conditions also strongly influence the presentation of ASD in particular individuals (Kraepel, Kenworthy, Popal, Martin, & Wallace, 2017). A number of these associated conditions are described below.

Neurodevelopmental Conditions

Neurodevelopmental conditions often co-occur with ASD. The sections that follow discuss the evidence base for the co-occurrence of intellectual disability, attention-deficit/hyperactivity disorder (ADHD), and tic disorder.

Intellectual Disability As noted previously, although older studies found that the majority of individuals with ASD also had an intellectual disability (Yeargin-Allsopp et al., 2003), more recent research suggests that only about 30% of children with ASD have a co-occurring intellectual disability. This decrease in the prevalence of intellectual disability corresponds with the expansion of the autism spectrum to include individuals with higher-functioning forms of autism and relatively intact cognition (CDC, 2016). Conversely, among individuals with intellectual disability, ASD is one of the most commonly co-occurring conditions, with one study finding that approximately one fifth (18%) of children with intellectual disability also had a diagnosis of autism (Tonnsen et al., 2016). In individuals with ASD, a co-occurring intellectual disability is associated with lower adaptive functioning and increased levels of repetitive and self-injurious behaviors (Matson & Shoemaker, 2009).

Attention-Deficit/Hyperactivity Disorder The *DSM-IV-TR* dictated that ADHD could not be diagnosed in a child with ASD. The *DSM-5*, published in 2013, now recognizes the disorders as two distinct, yet frequently co-occurring, conditions. The rate of co-occurrence remains less than clear, with estimates ranging from 16%–50% (Hanson et al., 2013; Rao & Landa, 2014; Sinzig, Walter, & Doepfner, 2009). Children with ASD

and co-occurring ADHD present with lower cognitive functioning, more severe social deficits, and lower adaptive functioning than children with ASD alone (Rao & Landa, 2014). They also demonstrate lower performance on measures of verbal working memory and delayed recall (Andersen, Hovik, Skogli, Egeland, & Oie, 2013). Investigators analyzing the often overlapping symptoms of the two disorders have attempted to explain the relationship between the core symptoms of inattention and impulsivity/hyperactivity in ADHD on the one hand and the social deficits and repetitive behaviors in ASD on the other (Sokolova et al., 2017). However, the clinical manifestation of ADHD and ASD as comorbid disorders tends to vary in different children. While some individuals show clear symptoms of inattention and hyperactivity/impulsivity, others show reduced sustained attention that could be attributed either to ADHD or to decreased social awareness or interest.

Tic Disorder Tic disorders, including persistent motor tic disorder, persistent vocal tic disorder, and Tourette disorder, are commonly associated with ADHD, obsessive-compulsive disorder, and disruptive behavior disorder (Scahill, Specht, & Page, 2014). In addition, up to 22% of children with ASD have a co-occurring tic disorder. ASD-associated tic disorders most often occur in children with comorbid intellectual disability, and there is a clear correlation between the level of intellectual disability and the prevalence of tic disorders (Canitano & Vivanti, 2007). It is important, but sometimes difficult, to distinguish between tics due to a tic disorder, compulsive behaviors due to obsessive compulsive disorder, and repetitive and stereotyped behaviors associated with ASD.

Psychiatric Conditions

Additional psychiatric disorders commonly co-occur in children with ASD. Until recently, the rates of co-occurrence were poorly understood due to both the difficulty of diagnosing psychiatric disorders, which may have symptoms that overlap those of ASD, and to the phenomenon of diagnostic overshadowing—the tendency to attribute the symptoms of a comorbid psychiatric condition to the primary developmental disability. Recent research has documented a very high rate of psychiatric comorbidity among children and adolescents with ASD. Studies show that 56%–95% of youth with autism meet criteria for a comorbid psychiatric disorder and the majority meets criteria for more than one psychiatric disorder (Joshi et al., 2010; Salazar et al., 2015; van Steensel, Bogels, & de Bruin, 2013). Although the association between IQ and level of psychiatric comorbidity is unclear, findings of higher rates

of psychiatric disorders in youth with ASD who *do not* have intellectual disability (Salazar et al., 2015; Selten, Lundberg, Rai, & Magnusson, 2015) suggests that these individuals may experience higher levels of anxiety or may simply be better able to verbalize their psychiatric symptoms. Although anxiety is the most common psychiatric comorbidity (Salazar et al., 2015), youth with ASD also show high rates of obsessive compulsive disorder (Griffiths, Farrell, Waters, & White, 2017), depression (McPheeters, Davis, Navarre, & Scott, 2011), bipolar disorder, and psychotic disorders (Selten et al., 2015).

Treatment of the comorbid psychiatric conditions in ASD has generally followed from the treatments used in youth without ASD, sometimes with and sometimes without clear evidence of the efficacy of these interventions in the ASD population. For example, CBT has been modified to meet the needs of individuals with ASD with the inclusion of social stories and visual supports as well as the use of well-structured workbooks. This modified approach to CBT has been found to be effective in addressing anxiety and obsessive compulsive disorder (Iniesta-Sepulveda et al., 2017; Ung, Selles, Small, & Storch, 2015). By contrast, medications such as selective serotonin reuptake inhibitors (SSRIs; see Chapter 38), which are widely used in people with ASD for the treatment of anxiety and obsessive-compulsive symptoms, have a less well-established evidence base (Vasa et al., 2016).

Genetic Disorders

ASD occurs with greater frequency in children with known genetic disorders. As discussed previously, approximately 5%–9% of individuals with autism who complete genetic testing (i.e., CMA) have clinically significant findings, with links to known genetic syndromes (Ho et al., 2016; McGrew et al., 2012; Tammimies et al., 2015). Overall, approximately 10% of individuals with autism have an associated genetic condition. Syndrome-associated autism may differ from idiopathic autism (autism due to unknown causes) with regard to physical, behavioral, and developmental characteristics (Moss & Howlin, 2009). In part, this difference may be due to the known correlation between the severity of intellectual disability and autism symptomatology (Matson & Shoemaker, 2009; Skuse, 2007); in other words, genetic disorders with an increased risk for intellectual disability also show an increased risk for ASD. However, across groups, the degree of intellectual disability associated with particular genetic disorders does not always account for the prevalence of ASD (Richards, Jones, Groves, Moss, & Oliver, 2015). In addition, as genetic testing becomes more sensitive and accessible, the number of known genetic disorders

with links to ASD may increase, while the line between syndromic and idiopathic autism becomes less clear.

A recent meta-analysis identified 12 known genetic syndromes with increased prevalence of autism phenomenology, with the highest prevalence of autism phenomenology found in females with Rett syndrome, a genetic disorder previously included under the classification of Pervasive Developmental Disorders in *DSM-IV-TR*. Information on these genetic disorders, their symptomology, and the prevalence of autism phenomenology is provided below. In addition, increased rates of autism have been linked to an ever-growing, though less-studied, list of genetic disorders including 2q37 deletion syndrome, 22q13 deletion syndrome, Duchenne and Becker's muscular dystrophy, hyopmelanosis of Ito syndrome, Joubert syndrome, Klinefelter syndrome, Lujan-Fryns syndrome, phenylketonuria syndrome, Potocki Lupski syndrome, PTEN mutations, Smith-Lemli-Opitz syndrome, Smith-Magenis syndrome, Sotos syndrome, Timothy syndrome, and Turner syndrome (Zafeiriou, Ververi, Dafoulis, Kalyva, & Vargiami, 2013). A number of these disorders are described in Appendix B.

Epilepsy

The co-occurrence of epilepsy in individuals with ASD has been well established (see Chapter 22). However, the rate of co-occurrence remains poorly defined, with higher rates in clinical samples (28%; Valvo et al., 2013) and lower rates in population studies (8.6%; Thomas, Hovinga, Rai, & Lee, 2017). In children with ASD, epilepsy is more common in females and in children with intellectual disability (Thomas et al., 2017) and is associated with increased deficits in social skills, even when compared with other children with autism and similar intellectual functioning (Ho et al., 2016). In addition, individuals with ASD are more likely to have abnormal EEG findings, even in the absence of clinical seizures (Valvo et al., 2013).

Associated Impairments

Children with ASD often have trouble with sleeping, feeding, and toileting. These impairments can cause significant functional limitations and are a source of stress for the child and the family. Management of children with autism should include assessment of these areas of functioning and help with accessing appropriate interventions and supports. In addition to the more formal interventions described below, Autism Speaks (www.autismspeaks.org) provides toolkits to help families and providers apply evidence-based strategies for addressing these difficulties.

Sleep Disorders Children with ASD are nearly twice as likely as typical peers to be diagnosed with a sleep disorder (Elrod & Hood, 2015; see Chapter 28). Overall, children with ASD have shorter than expected overall sleep times and more difficulty falling asleep, with sleep difficulties being more apparent in children with comorbid intellectual disability (Elrod et al., 2016). Disordered sleep is associated with behavioral dysregulation, including aggression, irritability, hyperactivity, and inattention (Mazurek & Sohl, 2016). Evidence supports the use of behavioral approaches, including individual counseling and parent-training programs (Malow et al., 2014). Melatonin, a naturally occurring substance that is sold as a supplement, may also be helpful for those children who do not respond to behavioral supports alone (Wright et al., 2011).

Feeding Disorders Although “picky” eating is quite common among young children, the prevalence of selective eating is much higher in children with ASD (Sharp et al., 2013). Children with autism will often reject foods based on textures, color, smell, brand, packaging, food group, or temperature (Marshall, Hill, Ziviani, & Dodrill, 2014), leading to diets that may be restricted to only one or two preferred foods and that may cause considerable stress for families. Beyond this selectivity, which appears to be associated with the characteristic behavioral/cognitive rigidity and sensory sensitivities of ASD, children with ASD may also struggle with the oral motor skills necessary for feeding (Marshall et al., 2014). Treatment for feeding disorders general falls into one of three categories: behavioral approaches (e.g., approaches using ABA-based techniques to introduce and reward eating new foods); sensory-based approaches (e.g., approaches such as the sequential oral sensory [SOS] approach, which uses systematic desensitization across a hierarchy of textures, within a play-based environment), and cognitive behavioral approaches (e.g., approaches combining exposure therapy with building strategies to cope with anxiety around food). See Chapters 10 and 29 on nutrition and feeding disorders for more information.

Gastrointestinal Symptoms and Toileting Difficulties

Gastrointestinal symptoms are often reported in children with ASD, including a higher rate of constipation, diarrhea, and abdominal pain (McElhanon, McCracken, Karpen, & Sharp, 2014). In addition, symptoms are associated with higher levels of social impairment and lower levels of social awareness (Gorrindo et al., 2012), reflecting the need for careful evaluation of children who may not be able to describe pain or discomfort. Associated with these gastrointestinal

symptoms, children with ASD generally take longer to toilet train and show higher rates of daytime and nighttime wetting and fecal incontinence (von Gontard, Pirrung, Niemczyk, & Equit, 2015). While it found insufficient evidence for specific treatment guidelines, a current consensus opinion recommended that children with ASD and gastrointestinal symptoms be worked up with the same care as children without ASD, with the additional caveats that these children may present with behavioral changes indicating pain or discomfort and may be best served by treatment incorporating both behavioral and medical care (Buie et al., 2010).

TREATMENT, MANAGEMENT, AND INTERVENTIONS

Early intervention has long been the mantra of ASD treatment. While there are no treatments that can cure autism, early and intensive intervention has been shown to positively impact both core impairments associated with autism and associated behavioral difficulties. Appropriate treatment differs according to a child's presentation and needs and typically changes over the course of development. Comprehensive treatment typically includes direct behavioral therapy and interventions to build communication, social, and adaptive skills and the provision of school-based services, as well as treatment by allied health professionals (e.g., speech-language pathologists) and treatment and monitoring by relevant medical disciplines (e.g., developmental pediatrics, neurology, and psychiatry). It should be noted that treatment of ASD is complicated by core difficulties with generalizing skills across different settings (Plaisted, 2001). For instance, individuals with ASD may demonstrate gains in targeted skills within the context of treatment or while treatment is occurring, but they often struggle to demonstrate skills outside of the immediate treatment context and may also have trouble maintaining these gains over time. Thus, many of the treatments described below as being *efficacious* may be limited in their *effectiveness*. Continual reinforcement of new skills is strongly recommended for individuals with ASD to support the maintenance of treatment gains.

Applied Behavior Analysis

The strongest evidence-based treatment for applied behavior analysis (ABA). ABA combines principles of learning and motivation with an understanding that consequences of behavior (whether positive or negative) reinforce or extinguish subsequent behavior (Granpeesheh & Tarbox, 2009). The behavioral principles of operant learning (see Chapter 34) were initially used in a

program for preschool children with autism developed by Dr. Ivar Lovaas (1987). His studies demonstrated that intensive early intervention that specifically teaches the component skills necessary for development was associated with subsequent typical classroom performance in almost half of the 20 children with autism studied (McEachin, Smith, & Lovaas, 1993). This model initially tested a 40-hour-per-week program that was based on individual therapy using discrete trial teaching, prompting, and reinforcement. Later studies reported qualitative improvement even in children who do not have the dramatic response to behavioral treatment as a result of comorbid intellectual disability (Smith, Eikeseth, Klevstran, & Lovaas, 1997). Generalization of skills to the home and classroom are an important component of the treatment plan (Foxy, 2008).

ABA may target a range of areas affected in autism, including communication, play skills, social interactions, activities of daily living (e.g., toileting, brushing teeth), and maladaptive behaviors (e.g., self-injury, aggression). It is specifically designed to be provided in the child's natural setting, which includes their home, school, and community. An ABA program is often highly intensive (e.g., as much as 30 hours per week), and consistency across settings is thought to be critical to the generalization of skills. The program is most often designed by a Board Certified Behavioral Analyst (BCBA; see Box 18.3) and implemented by a team of therapists. School programs may also be built on ABA principles. ABA includes a range of techniques and approaches, which vary in their primary goals and evidence for efficacy (Vismara & Rogers, 2010). There is strong and growing evidence of efficacy for some specific ABA programs for autism, including the Early Start Denver Model (Dawson et al., 2010), Pivotal Response Treatment (Koegel, Koegel, & Brookman, 2003), the Early Social Interaction Project (Wetherby et al., 2014), and the Joint Attention Symbolic Play Engagement and Regulation (JASPER) intervention (Kasari et al., 2006). There is also growing evidence that early intensive behavioral intervention, defined as 20–40 hours weekly of ABA and individualized instruction for children with autism under the age of 4, usually lasting for 2–3 years, may result in large developmental gains and a reduced need for long-term services (Odom et al., 2010; Reichow, Barton, Boyd, & Hume, 2014).

Speech-Language Therapy

Speech-language therapy is one of the most widely used treatments for autism. Speech therapy may target core language skills, such as following multi-step directions or speaking in grammatically correct sentences.

BOX 18.3 INTERDISCIPLINARY CARE**The Role of the BCBA**

Board Certified Behavioral Analysts (BCBAs) are individuals with extensive training and experience in applied behavioral analysis (ABA). For children with autism who receive ABA, BCBAs often take a leading role in designing and implementing the therapeutic program. Typically, a BCBA's work will begin with assessment of the child and their needs. This assessment can range from informal observation and discussion with the family about their concerns or goals to formal assessment, such as the Verbal Behavior Milestones Assessment and Placement Program. Once a BCBA has a solid understanding of a child's current level of functioning and behavioral needs, they will create a therapeutic program designed to build target skills and reduce problematic behaviors. The ABA program will include clear behavioral goals as well as a plan for charting behavior and assessing progress. Although some BCBAs provide direct therapy, many supervise behavior therapists who provide the direct therapy or train parents and teachers. Regardless of the model, the BCBA is continuously involved in assessing the child's progress and modifying the therapeutic program appropriately. In addition, for children with complex therapeutic needs, the BCBA may work as part of an interdisciplinary team, coordinating with occupational therapists, speech therapists, teachers, and special educators.

For young children with language delays or those who are minimally verbal, speech therapists may introduce AAC supports. AAC can be relatively "low-tech," such as the use of the Picture Exchange Communication System (PECS; Bondy & Frost, 2001; Charlop-Christy, Carpenter, Le, LeBlanc, & Kellet, 2002), in which children are taught to give pictures of desired items to others to communicate and to gradually sequence pictures into phrases or sentences. Spoken language is always paired with the PECS symbols, and children who use these approaches have been found to make greater gains in spoken language than those who do not. AAC can also be more "high-tech" for children who have long-term difficulties with spoken language, such as through the use of a voice-output device (VOD), in which the child touches a symbol or types words into a tablet or similar device that then "speaks" aloud for the child. Speech therapists are also well equipped to target pragmatic language and social difficulties, such as skills for greeting, conversations, and understanding and using non-verbal communication.

Social Skills Training

Social skills programs, particularly in group formats, are commonly offered for children and adolescents with autism, although research has not consistently supported the efficacy of all of these interventions (Reichow, Steiner, & Volkmar, 2012; White, Koenig, & Scahill, 2007). Peer-mediated approaches, particularly for young children, are among those with the best evidence of efficacy (Watkins et al., 2015; Wong et al.,

2015). In these programs, typically developing children are taught to model appropriate behaviors and support children with autism in playing with their peers. Social skills groups are popular and generally try to improve social skills by providing children and adolescents with direct instruction in interpreting and accurately responding to social cues, along with opportunities for practice with direct feedback on their performance. Among these, one of the best established is the Program for the Education and Enrichment of Relational Skills (Laugeson, Frankel, Gantman, Dillon, & Mogil, 2012), which teaches real-world social behaviors and utilizes instruction and feedback from both peers and adults. Social Stories (Gray, 2000) are also widely used by families, teachers, and professionals. These are simple stories with visual supports, adapted to a child's individual needs, that break down social situations for children to help them understand how they are expected to behave.

Occupational Therapy

At its core, the goal of occupational therapy is to help individuals to develop independence with everyday activities. This often includes a strong focus on addressing fine motor deficits that may interfere with daily functioning, such as difficulties fastening buttons or writing with a pencil. Fine motor skills are the area most commonly targeted by school-based occupational therapists. Increasingly, occupational therapists have begun to offer additional interventions to children with autism to address their other needs. Sensory integration

therapy and related techniques used to address the sensory processing problems in autism are common; however, it is important to note that there has been minimal research on these approaches and the research that has been conducted has been of poor quality; thus, sensory integration is not considered an evidence-based practice at this time (Lang et al., 2012). Some occupational therapists may also target social skills or executive functioning abilities, although these interventions are more often offered by other professionals (e.g., psychologists, speech-language pathologists, BCBA's, educators) who generally have more focused training and experience in the design and implementation of these interventions.

Medications

There are no medications that have been shown to treat the core impairments associated with autism (i.e., social communication deficits, rigid thinking, and repetitive behaviors). Medications can, however, play a role in addressing behavioral difficulties associated with autism and can help with comorbid conditions such as ADHD, anxiety, and depression (see Chapter 38). Risperidone (brand name: Risperdal) and aripiprazole (brand name: Abilify) are the only FDA-approved medications for treating the irritability commonly associated with autism, and both have a well-established evidence basis for this use (Hirsch & Pringsheim, 2016; Siegel & Beaulieu, 2012). Likewise, methylphenidate (common brand name: Ritalin) has been shown to be efficacious in addressing ADHD symptoms in children with autism, with emerging evidence as to the efficacy of nonstimulant medications, including the class of alpha-2 agonists (generic names: clonidine and guanfacine) and atomoxetine (brand name: Strattera), although with lower effect sizes than seen in studies of children with uncomplicated ADHD (Reichow, Volkmar, & Bloch, 2013). Evidence is less clear on the efficacy of SSRIs in treating repetitive behaviors or anxiety associated with autism (Carrasco, Volkmar, & Bloch, 2012; Vasa et al., 2016). In considering medication, it is important to understand that, relative to their neurotypical peers, children with autism have elevated rates of adverse effects and can experience adverse effects that are different than those seen in children without autism, including increased social withdrawal (Reichow et al., 2013).

School-Based Services

An appropriate educational program is an important aspect of treatment for children with autism. Many children with autism, particularly if they present with early language delays, will begin receiving educational

and therapeutic services through an individualized family service plan (see Chapter 31). These services are provided for children from 0–3 years under the Individuals with Disabilities Education Improvement Act of 2004 (IDEA; PL 108-446) and are geared toward providing early intervention services and parent training within the context of the home environment, often before any formal diagnosis.

From the ages of 3 to 21, most children with autism receive special education services through an individualized education program (IEP), which lays out specific goals for each child, as well as the services that will be provided to help them reach those goals (see Chapter 33). Eligibility for special education is determined not only by the presence of a disability, but also by the educational impact of that disability and the need for special education services. Thus, while many children with autism will qualify under the classification of Autism, others may qualify for additional classifications of Specific Learning Disability or Other Health Impairment for attention difficulties. In addition, for children with strong core cognitive and academic skills, the educational impact of their autism may not be apparent in their academic work, yet they will require special education instruction in social and communication skills to allow them to participate and learn within the social and verbal environment of the classroom. Regardless of the eligibility classification, it is important that the IEP for a child with autism go beyond academic difficulties to address broader difficulties with organization, social skills, communication, behavioral regulation, and adaptive skills.

The IDEA Act provides for a free appropriate public education that allows the child to make adequate yearly progress within the least-restrictive environment. Children with autism may be served in a variety of educational settings from mainstream classrooms to inclusion classrooms, self-contained classrooms or programs, and placement in nonpublic schools dedicated to serving children with autism. In deciding on an appropriate placement for a child with autism, there is often an attempt to balance the intensity of intervention needs against the benefits of integration with typical peers. Although the benefit of placement in the least-restrictive environment is an underlying principle of IDEA and of the special education field more broadly, the benefit of inclusive placement has not been fully studied for children with autism, with some studies showing gains in adaptive and cognitive functioning and others showing slower than expected progress (Ferraioli & Harris, 2011).

Although the inclusive environment may allow children with autism to learn how to participate in the community and to have models of

appropriate behavior, children with more intense social-communication deficits and highly self-directed attention may not benefit from this environment. These children may need the more highly structured environment provided by a self-contained placement, which can allow for instruction using highly specialized techniques (e.g., visually based learning, ABA-based teaching strategies) and can accommodate needs for low sensory and social stimulation in order to reduce stress.

In addition to outlining the primary placement, the IEP can also specify appropriate related services, which are necessary to allow children to gain the skills needed to benefit from classroom instruction. As with interventions outside of school, schools may offer a wide range of related services, including speech therapy, occupational therapy, physical therapy, behavior support services, social skills training, and counseling.

As a student nears graduation, his or her IEP must also include a transition plan, which lays out postgraduation goals for living, education, and employment and the steps needed to accomplish those goals, from participating in vocational classes to meeting with social service agencies and taking advanced classes (Chapter 33). Given the low rates of full employment among individuals with ASD, this transition plan is an essential part of school programming for young adults with autism. In the years leading up to graduation, the school programming should have a joint focus on academic skills and on the functional and vocational skills that will help the student maximize his/her independence as an adult. Even for the student with strong cognitive and academic skills, transition planning is necessary to ensure that the individual has the organizational and social skills needed in college and career settings.

Decisions about a child's special education program are made by the IEP team, of which the parents are an essential part. Therefore, it is important that parents understand the special education process and are able to bring their understanding of and priorities for their child to the educational team.

Complementary Health Approaches

Complementary health approaches (CHA) form a group of practices and products generally thought to be outside of conventional medical approaches, although often used in conjunction with more traditional treatments (Chapter 39). These practices are widely used in autism, with approximately one fourth of families reporting that they used at least one alternative treatment (Perrin et al., 2012). Many of these treatments have a basis in anecdotal evidence or

in studies without a clear control group or without clearly controlled, randomized trials. Reviews of the use of CHA in autism have largely noted limited findings and the need for more systematic research. Given the lack of a "cure" for ASD, families of these children may be particularly susceptible to these practices. The Association for Science in Autism Treatment (www.asatonline.org) and the National Standards Project (www.nationalautismcenter.org/national-standards-project/) provide up-to-date information about the evidence base for popular autism treatments. Providers are often most effective when they speak to families supportively and provide information about risks and benefits of various treatments. Families should be educated about and strongly advised against the use of CHA treatments known to be dangerous to children.

Dietary treatments are one of the most commonly used CHA treatments, most notably the gluten-free, casein-free (GFCF) diet, although concerns have been raised about the nutritional effects of these restricted diets. A recent, small double-blind study of the GFCF diet found no evidence of its effectiveness in addressing core symptoms of autism or behavior problems (Hyman et al., 2016). Similarly, reviews on the use of high levels of supplements, including B6 and omega-3 fatty acids, have noted limited research studies with inconclusive findings (James, Montgomery, & Williams, 2011; Nye & Brice, 2005). A newer approach, which involves the use of cord blood to treat autism symptoms, also has little research basis, although a recent study found that the treatment was well tolerated, paving the path for more robust clinical trials (Dawson et al., 2017). Likewise, although small in scale, trials with intranasal oxytocin show some promising, but inconsistent, results in addressing the core social deficits associated with autism (Anagnostou et al., 2012; Guastella et al., 2015).

In addition to these generally safe, alternative treatments, two widely used treatments have been found to be both lacking in evidence of effectiveness and potentially harmful: 1) chelation therapy, which aims to remove heavy metals from the blood, but can lead to serious kidney damage (James, Stevenson, Silove, & Williams, 2015), and 2) hyperbaric oxygen therapy, which can lead to damage to the ear (Xiong, Chen, Luo, & Mu, 2016).

OUTCOMES

The heterogeneity among individuals with ASD ensures that outcomes likewise vary significantly. The sections that follow briefly trace the variability of outcomes from identification to adulthood.

Developmental Trajectories Children with autism show a great deal of variability in their developmental trajectories, although much of that variability appears to be set fairly early in development. With regard to the initial presentation of autism, children generally fall into one of two groups: those with early onset of symptoms, exhibiting early and widespread developmental disruption, and those with later onset of symptoms, who have a period of apparent typical development followed by slower development or regression. However, regardless of the age of onset, symptoms and presentations are often similar by 2 years of age (Landa, Gross, Stuart, & Faherty, 2013). Once diagnosed, for many children, their trajectories are consistent with their initial presentation (Lord, Bishop, & Anderson, 2015). While children who present with lower nonverbal skills and more severe autistic symptoms show slower development of core language, intellectual, and social skills, children who initially present with higher nonverbal skills show strong progress, with clear improvement in language and intellectual skills, sometimes to the point of “catching up” with their typically developing peers (Fountain, Winter, & Bearman, 2012; Pickles, Anderson, & Lord, 2014). Although a small group of “late bloomers” show rapid rates of developmental progress between the ages of 3 and 5, much of the difference between trajectories is evident between the ages of 2 and 3. Likewise, although language continues to develop, there is little change in language trajectory after the age of 6. In terms of long-term trajectories, the majority of individuals with autism continue to show a decline in symptom severity as they progress through childhood and adolescence (Howlin & Magiati, 2017), and approximately 70% achieve functional language on at least a 5-year-old level (Pickles et al., 2014).

Optimal Outcomes Although autism is generally considered a lifelong disability, approximately 10% of individuals who initially and accurately were diagnosed with autism at a young age will lose their autism diagnosis later in life (Anderson, Liang, & Lord, 2014). In early development these children are more likely to have received treatment at a young age and are characterized by higher verbal IQ, lessening of repetitive behaviors between the ages of 2 and 3, and a trend toward improved social skills during that same period (Anderson et al., 2014). For these individuals, social and communication skills continue to improve through childhood and early adolescence. As adults, these individuals, previously diagnosed with autism, appear to have social, communication, and language skills comparable to typically developing peers (Fein et al., 2013), although they do have higher rates of ADHD and anxiety (Orinstein et al., 2015).

Adults with Autism Outcomes among adults with autism are quite variable. While some individuals are able to live fully independent lives with a long-term partner or spouse, many adults with autism continue to need assistance in many domains. Intellectual functioning and language skills are the strongest predictors of outcomes for adults with autism. Few individuals with intellectual disability, or who lack functional language, are able to live on their own or achieve independent employment. However, even individuals with average or above-average intellectual functioning show low rates of employment, low levels of independent living, and few social contacts, although studies show variability in the prevalence of these difficulties (Farley et al., 2009; Howlin & Magiati, 2017).

Unfortunately, these outcome measures for individuals with autism but without intellectual disability do not appear to have shown significant improvement over the past decade despite the increase in available services for young children with autism and higher rates of individuals achieving advanced, post-high school education (Howlin & Magiati, 2017). In addition, as a whole, individuals with autism show high rates of psychiatric comorbidity (Gadke, McKinney, & Oliveros, 2016) and higher levels of mortality, with a lower age of death and a death rate that is nearly double that of the typically developing population (Howlin & Magiati, 2017). These mortality statistics reflect both the comorbidities associated with autism and the difficulties that individuals with autism may have in accessing medical care. In many ways, the outcomes of adults with autism reflect the essential gap between intellectual functioning and adaptive skills, with even individuals with average to above-average IQ showing global adaptive deficits (Kenworthy, Case, Harms, Martin, & Wallace, 2010). However, these outcomes also highlight the dearth of services or interventions geared toward adults with autism and toward improving everyday functioning in this population.

SUMMARY

- ASD is a neurodevelopmental disorder characterized by impairment in core social-communication abilities, along with the presence of restricted, repetitive patterns of behavior, interest, and activity.
- Although ASD is present from birth, first concerns are typically not apparent until between the ages of 1 and 2. For children with stronger language and core cognitive skills, concerns may not become apparent until much later, when social demands outpace their abilities.

- The majority of children with ASD have comorbid neurodevelopmental or psychiatric conditions that impact their functioning. Intellectual disability and ADHD are two of the most common, co-occurring conditions.
- Early diagnosis and treatment of ASD have been shown to improve many areas of functioning and to decrease the need for later services. Comprehensive treatment often includes intensive behavioral intervention as well as treatments to build social and communication skills.

CHAPTER 19

Attention-Deficit/ Hyperactivity Disorder

Marianne Glanzman and Neelam Kharod Sell

Upon completion of this chapter, the reader will

- Be familiar with the diagnostic criteria for attention-deficit/hyperactivity disorder
- Be aware of some of the causes of inattention and hyperactivity
- Understand the components of the diagnostic process
- Be aware of commonly associated symptoms and conditions
- Know the different approaches to management
- Understand the natural history and outcomes for this disorder

Attention-deficit/hyperactivity disorder (ADHD) is one of the most prevalent neurodevelopmental/mental health conditions in childhood. It is characterized by developmentally inappropriate levels of inattention and distractibility and/or hyperactivity and impulsivity that cause impairment in adaptive functioning at home, school, and in social situations. ADHD often persists into adolescence and adulthood. Treatment, including educational and psychosocial interventions, medication, and lifestyle modifications, can substantially improve short-term behavioral, academic, and social functioning. Optimal outcomes, however, have not been achieved, in part because sustained multimodal treatment is not widely accessible. Our understanding of the brain and genetic bases for the symptoms of ADHD has progressed rapidly over the past 30 years and may ultimately provide new insights into prevention and treatment.

■ ■ ■ CASE STUDY

Ricky, age 7, is in second grade. His teacher reports that he is having great difficulty learning to read. He also is quite disruptive in class, frequently not listening to directions, getting out of his seat, making tangential comments, and talking out of turn. His first-grade teacher reported similar problems, but these difficulties were attributed to him having to adjust to the new school, as he had attended a Montessori kindergarten previously. His parents and soccer coach have also noticed problems with his ability to follow directions and pay attention. Ricky was adopted shortly after birth, so there is no family history available. He has, however, always had a “difficult” temperament. He was a colicky infant with poor sleep patterns. As a preschooler, he was demanding and inflexible, and he would exhaust all those around him with his need to negotiate when he was asked to comply with a directive.

His parents and teachers feel that he is still quite immature and demanding, as he requires much more attention than other children his age in order to accomplish even routine daily activities.

A comprehensive evaluation revealed that Ricky has ADHD, combined presentation (ADHD-C) and a learning disability in reading, though he is intellectually gifted. Ricky was considered to be at significant risk for both academic and behavior difficulties; as such, his interdisciplinary team decided to put a multimodal treatment plan into place. Stimulant medication was started, and it proved dramatically helpful at school, as well as on weekends and school vacations, in improving functioning in social situations and activities of daily living. Counseling was also begun, focusing on the development of a consistent behavior management plan at home and school, as well as social skill instruction. At school, Ricky received resource room assistance for reading and language arts, enrichment programming in math, and weekly meetings with the school counselor for a social skills group.

Thought Questions:

How might a parent, teacher, or doctor of a school-age child distinguish inattention related to ADHD from inattention related to other causes? How might professionals counsel the parents of a child newly diagnosed with ADHD regarding treatment options? When the parents of a newly diagnosed child ask, "What does the future hold for our child with ADHD?", how should a professional respond to convey both hopefulness and realism?

DIAGNOSIS AND ADHD PRESENTATIONS

ADHD is a neurobehavioral syndrome; as of 2018, there are no available medical or psychological tests to definitively make the diagnosis. Instead, the diagnosis depends on "ruling in" symptoms of ADHD and "ruling out" other causes of the symptoms through the use of interviews and rating scales to systematically collect information from parents, teachers, and (older) children (which will be discussed in a section that follows titled "The Evaluation Process") (American Academy of Pediatrics [AAP], 2011).

The current diagnostic criteria consist of two major clusters of symptoms: inattention and hyperactivity/impulsivity. These criteria, outlined in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)*, of the American Psychiatric Association (APA, 2013), are shown in Table 19.1. In order to meet criteria for the diagnosis, children must have six of the nine symptoms in either or both categories. Those 17 years of age and older are only required to have five

symptoms. Additional requirements for all presentations include 1) evidence of several symptoms before age 12 that have persisted for at least 6 months; 2) occurrence of several symptoms across multiple settings (i.e., school and home); 3) functional impairment as a result of symptoms in academic, social, or adaptive/occupational activities; and 4) symptoms cannot be better accounted for by another disorder such as a psychotic, mood, personality, or substance use disorder (APA, 2013).

Two additional diagnostic categories may be used when full criteria are not met. Other Specified ADHD is used when some, but not all, required symptoms are present. In addition, 1) the symptoms must be causing functional impairment, 2) the individual must not meet criteria for another neurodevelopmental disorder, and 3) the clinician must be able to articulate what is missing from the full criteria. For example, a 12-year-old child without another neurodevelopmental diagnosis who has five rather than six of the required symptoms and declining academic performance attributable to inattentive symptoms would receive this diagnosis. Unspecified ADHD is used when symptoms characteristic of ADHD are present and cause functional impairment and there is no other neurodevelopmental diagnosis but the clinician does not choose to specify what requirements are missing. This diagnosis is most often used when insufficient information is available to determine whether or not full criteria are met.

Changes in the diagnostic formulation from the *Diagnostic and Statistical Manual, Fourth Edition, Text Revision (DSM-IV-TR; APA, 2000)*, to the current *DSM-5 (APA, 2013)* include further specifying examples of symptoms to improve relevance to adolescents and adults, increasing the required age at which symptoms are first noted to be impairing from 7 to 12, and reducing the number of required symptoms from 6 to 5 in older adolescents and adults (Dalsgaard, 2013).

ADHD Combined Presentation is the most commonly diagnosed presentation in clinical samples and the most studied presentation of ADHD. It is associated with social impairment, increased prevalence of coexisting internalizing (anxiety and mood) and externalizing (oppositional defiant and conduct) disorders, and academic underachievement (Baeyens, Roeyers, & Walle, 2006; Spencer, Biederman, & Mick, 2007).

ADHD Inattentive Presentation is the most common presentation in broad epidemiologic samples (excluding preschoolers; Willcutt, 2012). It refers to individuals who do not display significant levels of hyperactivity but have significant problems in maintaining attention. The ratio of girls to boys with this

Table 19.1. Diagnostic criteria for attention-deficit/hyperactivity disorder

- A. A persistent pattern of inattention and/or hyperactivity-impulsivity that interferes with functioning or development, characterized by (1) and/or (2):
1. Inattention/distractibility: Six (or more) of the following symptoms that have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:
Note: The symptoms are not solely manifestations of oppositional behavior, defiance, hostility, or failure to understand tasks or instructions. For older adolescents and adults (those ages 17 or older), five symptoms are required.
 - a. Often fails to give close attention to details or makes careless mistakes in schoolwork, work, or other activities (e.g., overlooks or misses details, work is inaccurate).
 - b. Often has difficulty sustaining attention in tasks or play activities (e.g., has difficulty remaining focused during lectures, conversations, or lengthy reading).
 - c. Often does not seem to listen when spoken to directly (e.g., mind seems elsewhere, even in the absence of any obvious distraction).
 - d. Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (e.g., starts tasks but quickly loses focus and is easily sidetracked).
 - e. Often has difficulty organizing tasks and activities (e.g., difficulty managing sequential tasks; difficulty keeping materials and belongings in order; has messy, disorganized work; has poor time management; fails to meet deadlines).
 - f. Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (e.g., schoolwork or homework; for older adolescents and adults, preparing reports, completing forms, reviewing lengthy papers).
 - g. Often loses things necessary for tasks or activities (e.g., school materials, pencils, books, tools, wallets, keys, paperwork, eye-glasses, mobile telephones).
 - h. Is often easily distracted by extraneous stimuli (for older adolescents and adults, may include unrelated thoughts).
 - i. Is often forgetful in daily activities (e.g., doing chores, running errands; for older adolescents and adults, returning calls, paying bills, keeping appointments).
 2. Hyperactivity and impulsivity: Six (or more) of the following symptoms that have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:
Note: The symptoms are not solely manifestations of oppositional behavior, defiance, hostility, or failure to understand tasks or instructions. For older adolescents and adults (those ages 17 or older), five symptoms are required.
 - a. Often fidgets with hands or feet or squirms in seat.
 - b. Often leaves seat in classroom or in other situations in which remaining seated is expected (e.g., leaves his or her place in the classroom, in the office or other workplace, or in other situations that require remaining in place).
 - c. Often runs about or climbs excessively in situations in which it is inappropriate (**Note:** In adolescents or adults, may be limited to feeling restless).
 - d. Often unable to play or engage in leisure activities quietly.
 - e. Is often “on the go,” acting as if “driven by a motor” (e.g., is unable to be or uncomfortable being still for extended time, as in restaurants, meetings; may be experienced by others as being restless or difficult to keep up with).
 - f. Often talks excessively.
 - g. Often blurts out answers before a question has been completed (e.g., completes people’s sentences; cannot wait for turn in conversation).
 - h. Often has difficulty waiting his or her turn (e.g., while waiting in line).
 - i. Often interrupts or intrudes on others (e.g., butts into conversations, games, or activities; may start using other people’s things without asking or receiving permission; for adolescents or adults, may intrude into or take over what others are doing).
- B. Several inattentive or hyperactive-impulsive symptoms were present prior to age 12 years.
- C. Several inattentive or hyperactive-impulsive symptoms are present in two or more settings (e.g., home, school, or work; with friends or relatives; in other activities).
- D. There is clear evidence that the symptoms interfere with, or reduce the quality of, social, academic, or occupational functioning.
- E. The symptoms do not occur exclusively during the course of schizophrenia or another psychotic disorder and are not better explained by another mental disorder (e.g., mood disorder, anxiety disorder, dissociative disorder, personality disorder, substance intoxication or withdrawal).
- Specify whether:*
- 314.01(F90.2) Combined presentation: If both Criterion A1 (inattention) and Criterion A2 (hyperactivity-impulsivity) are met for the past 6 months.
- 314.00 (F90.0) Predominantly inattentive presentation: If Criterion A1 (inattention) is met but Criterion A2 (hyperactivity-impulsivity) is not met for the past 6 months
- 314.01 (F90.1) Predominantly hyperactive-impulsive presentation: If Criterion A2 (hyperactivity-impulsivity) is met and Criterion A1 (inattention) is not met for the past 6 months.
- Specify if:*
- In partial remission: When full criteria were previously met, fewer than the full criteria have been met for the past 6 months, and the symptoms still result in impairment in social, academic, or occupational functioning.
- Specify current severity:*
- Mild: Few, if any, symptoms in excess of those required to make the diagnosis are present, and if symptoms result in no more than minor impairments in social or occupational functioning.
- Moderate: Symptoms or functional impairment between “mild” and “severe” are present
- Severe: Many symptoms in excess of those required to make the diagnosis, or several symptoms that are particularly severe, are present, or the symptoms result in marked impairment in social or occupational functioning.

presentation is slightly higher than for the other presentations, and it is usually identified at a later age. The pattern of psychiatric comorbidity also differs from that of the combined presentation with fewer oppositional disorders or conduct disorders, but with more anxiety and mood disorders. Educational impairments are the most prominent difficulty experienced by this group (Baeyens et al., 2006; Barkley, 1998; Stefanatos & Baron, 2007). There is some evidence to suggest that the specific nature of inattention in this presentation may differ from the inattention shown by those with the combined presentation. A “slow” cognitive tempo is characteristic of some individuals with the inattentive presentation, and their inattention may be characterized by slow processing speed rather than distractibility (Becker et al., 2016).

ADHD Hyperactive/Impulsive Presentation was first identified in the *DSM-IV* (APA, 1994) and refers to children who do not display significant levels of attention problems in the presence of hyperactivity and impulsivity. The specific presentations of ADHD are not necessarily stable over time (Lahey, Pelham, Loney, Lee, & Willcutt, 2005). In particular, the hyperactive/impulsive presentation is most often diagnosed in preschool age boys and may change over time to the combined presentation as young children may have not yet reached an age at which attention problems are impairing (Greenhill, Posner, Vaughan, & Kratochvil, 2008). There is ongoing research regarding the two major symptom domains of ADHD. Some research suggests that the inattentive and hyperactive/impulsive presentations have different genetic influences, although both are highly heritable (Nikolas & Burt, 2010).

While there is general agreement on the conceptualization of ADHD as a disorder with specific core features and a desire to specify and quantify symptoms as much as possible, there is also agreement that a clear dividing line between presence and absence of the disorder does not exist. ADHD is increasingly recognized as the severe end of a symptom continuum, with a wide range in the degree of subthreshold symptom severity (Balázs & Keresztény, 2014; McLennan, 2016). The concept of a continuum is supported by genetic studies that show that genetic differences conferring risk for ADHD are more commonly present, not only in those with the diagnosis, but also in those with some symptoms (Middeldorp et al., 2016; Stergiakouli et al., 2015). There are also developmental studies that show that the youngest children in a specific grade are more likely to be diagnosed with ADHD than the oldest children in that grade (Sayal, Chudal, Hinkka-Yli-Salomäki, Joelsson & Sourander, 2017).

PREVALENCE AND EPIDEMIOLOGY

Prevalence is the proportion of a population who have a specific characteristic, or in this case, diagnosis, in a given time period. Point prevalence refers to the presence of the diagnosis at the time of the study, whereas lifetime prevalence, more commonly used in adults, refers to a history of ever having had the diagnosis. The prevalence of ADHD varies based on the population studied and the methods used. Studies based on endorsement of symptoms on questionnaires typically result in higher prevalence rates than studies that include a diagnostic interview to assess for other possible causes of symptoms and for a significant level of functional impairment (Polanczyk, Salum, Sugaya, Caye, & Rhode, 2015). Studies that use community, or population-based, samples also show higher rates, as a substantial group may have been previously undiagnosed (Rowland et al., 2015). Finally, the use of *DSM-5* rather than *DSM-IV* criteria increases prevalence rates due to the later age of onset allowed and a reduced number of symptoms required in older adolescents and adults (Vande Voort, He, Jameson, & Merikangas, 2014).

In the previous edition of this text, the estimated prevalence of ADHD in school-age children in the United States was 7%–10%. Newer studies suggest a rate of 8%–15% (McKeown et al., 2015; Rowland et al., 2015; Wolraich et al., 2014). It remains controversial as to whether this increase is due to the change in diagnostic criteria described above or whether there is a true increase in prevalence. A recent meta-analysis of world-wide studies (Polanczyk, Willcutt, Salum, Kieling, & Rohde, 2014) suggests that when methodological characteristics of the studies are taken into account, there has not been a true increase in the rate of ADHD. World-wide studies suggest a pooled prevalence of 3%–7% (Polanczyk et al., 2015; Thomas, Sanders, Doust, Beller, & Glasziou, 2015).

There continues to be significant variation in the rate of identification of ADHD in different populations. The rate of clinical identification is somewhat lower in the United States in Hispanic and African American children than for Caucasian children for reasons that likely include differences in cultural attitudes and ascertainment as well as differences in access to care, although prevalence rates of symptoms are similar (Alvarado & Modesto-Lowe, 2017; APA, 2013; Pastor, Reuben, Duran, & Hawkins, 2015). Identification rates of ADHD have consistently been lower in the United Kingdom (1.4%–3%) than in the United States, where different diagnostic criteria are used and underidentification has been hypothesized (Taylor, 2017; Thapar & Cooper, 2016). Studies in other European countries

suggest intermediate rates between the United Kingdom and the United States (Taylor, 2017).

Prevalence rates in preschoolers and adults are derived from fewer studies. In preschoolers, prevalence estimates using *DSM-III* (APA, 1980) or *DSM-IV-TR* criteria range from 2%–5.7% (Egger & Angold, 2006) with slightly lower rates (1.9%) in a Scandinavian sample (Wichstrøm et al., 2012). In adults, pooled prevalence estimates are approximately 5% (Willcutt, 2012). These studies were done using *DSM-IV* criteria, and changes to *DSM-5* are likely to result in an increase in prevalence in older adolescents and adults (Dalsgaard, 2013).

In clinic-referred samples, the ratio of boys to girls diagnosed with ADHD ranges from 6 to 1 to 12 to 1, although in community samples that ratio is closer to 2 to 1 in children and 1.6 to 1 in adults (APA, 2013; Biederman et al., 2005). It is presumed that boys are referred more often than girls due to a higher rate of co-occurring aggressive behavior and oppositional and conduct disorders. Girls, on the other hand, may be more likely than boys to be referred because of the inattentive presentation and associated learning and internalizing disorders (mood and anxiety disorders), as well as disordered eating (Quinn, 2008; Rucklidge, 2010).

ADHD is estimated to persist from preschool into childhood, from childhood into adolescence, and from adolescence into adulthood in the majority of cases. The diagnosis is estimated to persist into adulthood in 2%–5% of the population in the United States (Barkley, 2010).

CLINICAL PRESENTATION

The presenting symptoms of ADHD tend to differ with age. During the preschool years, excessive activity level and impulsivity are typically the most prominent symptoms. This is often accompanied by cognitive inflexibility and emotional dysregulation. In combination, these symptoms may lead to impulsive aggression. Given the high activity level and short attention span of the typical preschooler, only children severely affected with ADHD will differ sufficiently from the developmental norm to fully meet the criteria for the disorder. Children in this age group who meet diagnostic criteria for ADHD have a greater rate of developmental delay, intellectual disability, coordination disorder, language disorders, autism spectrum disorder (ASD), and comorbid internalizing and externalizing disorders (Chacko, Wakschlag, Hill, Danis, & Espy, 2009; Smith et al., 2017; Tandon & Pergjika, 2017). In order to make an accurate diagnosis, children who present in the preschool period should be carefully assessed for hearing and vision deficits and the developmental disorders mentioned

above, all of which have some similarities in presentation to ADHD (Daley, Jones, Hutchings, & Thompson, 2008). The majority of preschoolers diagnosed with ADHD will continue to meet criteria for the disorder in elementary school (Faraone, Biederman, & Mick, 2006; Lahey et al., 2004; Riddle et al., 2013). Symptom severity, cognitive ability, and family factors are key predictors of persistence into school age (Caye et al., 2016; Cherkasova, Sulla, Dalena, Ponde, & Hechtman, 2013).

Upon entering elementary school, problems with listening and compliance, task completion, work accuracy, and social interactions are common concerns of parents and teachers. Determining whether learning problems are caused by ADHD, coexist with ADHD, or are causing ADHD symptoms is an important component of making the diagnosis and developing a treatment plan in school-age children. While no “foolproof” formula for doing so exists, a careful history about timing and setting of symptoms and response to interventions can help clinicians develop a working hypothesis.

In adolescence, observable hyperactivity may decline significantly (Faraone et al., 2006; Lahey et al., 2005; Riddle et al., 2013). Concerns often focus around work completion, organization, and following rules. Approximately 65% of children with ADHD diagnosed early in childhood continue to meet the criteria for the disorder in adolescence, while an additional group will meet criteria for other specified ADHD or unspecified ADHD because of a reduced number of symptoms. The same factors that predict persistence from preschool into childhood continue to predict persistence into adolescence, with the addition of comorbid externalizing disorders predicting both persistence of ADHD symptoms and degree of impairment (Caye et al., 2016; Cherkasova et al., 2013).

Occasionally, individuals are not diagnosed with ADHD until adolescence, although they must have had symptoms by history that were impairing in childhood in order to meet current diagnostic criteria. Children who were able to cope during the early grades—typically because of low levels of hyperactivity/impulsivity; strong intellectual, social, athletic, or other strengths; and supportive families and school personnel—may present in adolescence. Their attentional/executive systems may finally be overwhelmed by the demands for processing increased volumes of reading and writing as well as the complex social, time management, organizational, and higher-order thinking and language processing skills required of them in high school.

Recent birth cohort studies using questionnaires suggest that a substantial percentage of older adolescents and adults who were not diagnosed with ADHD in childhood had significant symptoms of ADHD at

the time of the study, suggesting that there might be an adult-onset form of the disorder (Agnew-Blais et al., 2016; Caye et al., 2016; Moffitt et al., 2015). However, prospective direct evaluation follow-up of a community sample of children without ADHD showed that up to 95% of those who met symptom criteria of ADHD in late adolescence/early adulthood by questionnaire in the absence of a childhood diagnosis had either fluctuations in cognitive symptoms or another disorder that could account for the symptoms, the most common being substance use disorder. Adolescent late-onset cases were often transient and limited to adolescence (Sibley et al., 2018).

Across all age groups, the most common factors predicting persistence into the subsequent age group are severe symptoms of ADHD; treatment for ADHD (which may be a marker of severity); the presence of disruptive behavior, oppositional defiant disorder, conduct disorder, or depression; and a family history of persistent ADHD (Caye et al., 2016; Riddle et al., 2013).

COMMON COEXISTING CONDITIONS

There are several conditions that occur more frequently in individuals with ADHD than in individuals without it, typically referred to as “comorbid” or “coexisting” conditions. Less frequently, another condition mimics ADHD and is the primary cause of inattentive or hyperactive symptoms rather than coexisting with ADHD (see later section in this chapter on the evaluation process). Coexisting conditions are important to identify during an evaluation because 1) they will often require additional or different treatment and, 2) unless treated, they may prevent adequate treatment of ADHD.

More than half of children and adolescents with ADHD presenting to a specialty clinic will have a coexisting disorder, including externalizing disorders (oppositional and conduct disorders), internalizing disorders (mood and anxiety disorders), learning disorders, and tic disorders (Pliszka, 2000; Singer, 2005). Approximately 25% will have more than one coexisting disorder (Jensen & Steinhausen, 2015). In clinical samples, most will have an externalizing behavior disorder, such as oppositional defiant disorder (approximately 60%; characterized by noncompliance and defiance of authority) or conduct disorder (approximately 20%; characterized by more serious antisocial behaviors) (Conner, Steeber, & McBurnett, 2010; Jensen & Steinhausen, 2015). There is an association between hyperactive/impulsive symptoms and oppositionality (Wood, Rijdsdijk, Asherson, & Kuntsi, 2009). Estimates of internalizing disorders (anxiety and depression) in ADHD vary considerably from study to study, ranging from 14%–83%. Anxiety

disorders occur in approximately 15%–35% of children with ADHD and may include separation anxiety, generalized anxiety, phobic, or obsessive compulsive disorder (OCD; Schatz & Rostain, 2006). Comorbid anxiety and ADHD may lead to increased school problems and functional impairment as compared with either disorder alone (Hammerness et al., 2009a). Depression is relatively common in the general population, with rates of approximately 2% in childhood and increasing to up to as high as 24% in some studies in adolescence. There appears to be an increased risk for unipolar depression in individuals with ADHD, but this varies widely with study design. What is consistent is an increasing risk in adolescence and young adulthood and in those with a family history of depression (Meinzer, Pettit, & Viswesvaran, 2014). Childhood bipolar disorder is difficult to diagnose due to a gradual and less distinct onset of symptoms compared with the symptoms described for adults in the *DSM-5*. Children are likely to have episodic irritability or atypical mood, intermittent explosiveness, psychomotor agitation characterized by talkativeness or motor restlessness, and signs of disordered thinking (Galanter & Leibenluft, 2008). There is evidence that juvenile onset of depression and subthreshold symptoms of depression and mania may be predictors of bipolar disorder in children (Faedda et al., 2015). Bipolar disorder has a lifetime prevalence of approximately 2% in adults, with most reporting onset of symptoms before the age of 18 years (Marangoni, De Chiara, & Faedda, 2015). It is particularly difficult to distinguish from ADHD due to an overlap in several symptoms, especially when internalizing and externalizing disorders coexist with ADHD.

Three main learning disabilities have been studied in relation to ADHD-specific disorders of reading, mathematics, and written language. Disorders of reading (including dyslexia, a disorder of reading at the word reading level) are the most common—and most studied—learning disability. The prevalence of a specific reading disability (RD) among students with ADHD ranges from 25%–48%. Reading disorders and ADHD have both distinct and shared neuropsychological factors that impact the rapid retrieval of linguistic information that is critical for fluent reading. While weak phonological processing and rapid naming are specific to reading disorder, and inattention and poor response inhibition are specific to ADHD, both share features of slow processing speed and weak verbal working memory. Approximately 11%–30% of children with ADHD have comorbid specific mathematics disorders, which may manifest as difficulty with calculation, problem-solving, or both. Math disorders may be related to weak visuospatial working memory in particular.

Approximately 55%–64% of children with ADHD have disorders of written language. In addition to inattention, the higher rates of weakness in visual-motor coordination, fine motor coordination, working memory, organization, and planning seen in ADHD likely contribute to the high rate of comorbidity (Pham & Riviere, 2015).

Tic disorders, including transient, chronic motor, or vocal tic disorder, or Tourette syndrome occur in as many as 20% of school-age children at some point in time, with transient tics being the most common and Tourette syndrome being the least common (Scahill, Specht, & Page, 2014). Tics occur at higher rates in children with ADHD, with about a 20% current (point) prevalence (Schlander, Schwarz, Rothenberger, & Roessner, 2011; Yoshimasu et al., 2012). Conversely, approximately 50% of children with tic disorders have ADHD (Cooke & So, 2016). Tics can occur on a spectrum from mild (which may not even be reported by parents) to the more severe (in which tics have important physical, emotional, and social impact). Group data show no increase in rates of tic disorders in children with ADHD on psychostimulant medications, but these medications may increase tics in specific individuals (Erenberg, 2006). In children with ADHD and Tourette syndrome, ADHD often appears first, and ADHD typically causes greater functional impairment than does the tic disorder (Cooke & So, 2016; Denckla, 2006; Singer, 2005). Persistent tics are often associated with externalizing and internalizing disorders, including obsessive-compulsive disorder as well as ADHD (Kraft et al., 2012; Pollak et al., 2009; Scahill et al., 2014).

In prior editions of the *DSM*, the presence of ASD was an exclusionary criterion for diagnosing ADHD; thus, the two diagnoses could not co-exist. The current edition allows both diagnoses when criteria are met for both. Given the overlap in social deficits and poorly regulated behavior, determining whether ASD is present instead of, or in addition to, ADHD can be difficult; this is discussed further in the later section on evaluation in this chapter. ASD is estimated to be present in 20%–65% of children with ADHD, and ADHD is estimated to be present in 30%–80% of children with ASD (Sokolova et al., 2017; van der Meer et al., 2012). Both genetic and neuropsychological factors (such as inattention, executive dysfunction, motor speed and variability, emotion recognition, and detail-focused processing) likely underlie the high rates of coexistence. It has even been hypothesized that ASD is the severe end of a single diagnostic continuum that includes ADHD, since within a population sample ADHD subgroups with and without ASD symptoms exist but all ASD subgroups have ADHD symptoms (van der Meer et al., 2012).

More severe ADHD symptoms and the male gender are associated with a higher risk of ASD (Green et al., 2015); attention dysfunction (especially maintaining and switching focus) is a particularly important common factor in ADHD and ASD (Sokolova et al., 2017; Visser, Rommelse, Greven, & Buitelaar, 2016). In children with both diagnoses, those diagnosed with ADHD as young children are diagnosed with ASD 3 years later on average, and they are more than 30 times more likely to be diagnosed after age 6 (Miodovnick, Harstad, Sideridis & Huntington, 2015). The highest rate of coexistence occurs in adolescence, likely due to a significant increase in the demands for social adaptability and executive skills during the transition process to independence (Hartman, Geurts, Franke, Buitelaar, & Rommelse, 2016).

Developmental coordination disorder (DCD), defined as a significant impairment in the acquisition and execution of coordinated motor skills leading to impairment in daily activities, is one of the more frequent conditions coexisting with ADHD. Impaired motor coordination can have a significant effect on the acquisition of adaptive, athletic, and writing skills, further impairing daily, social, and academic functioning. Although it is thought to occur in 5%–20% of the childhood population, it is seen in 30%–50% of children with ADHD (Cairney, Veldhuizen, & Szatmari, 2010). Boys are diagnosed two to seven times more often than girls. Core ADHD symptoms such as high activity level, impulsivity, and distractibility, as well as symptoms associated with ADHD, such as variable reaction time, weak working memory, and slow processing speed, can also contribute to difficulties with motor performance. Distinguishing the two etiologies of motor impairments in children with ADHD (secondary versus coexisting DCD) is a subject of ongoing research (Goulardins, Marques, & De Oliveira, 2017).

ASSOCIATED IMPAIRMENTS

Individuals with ADHD often have associated impairments. These may include symptoms that are not related to the core symptoms of ADHD or symptoms of coexisting disorders that do not meet full criteria for a diagnosis. Nonetheless, they can be significantly impairing and may require additional interventions. These include impairments in executive, language, social, academic, and adaptive functions; emotional regulation; and sleep.

Executive functions (EFs; see Chapter 13) include sustaining and shifting attention, being able to hold and manipulate information in order to complete a task (working memory), organizing and prioritizing

incoming information, planning ahead, self-monitoring, and inhibiting responses (Martinussen, Hayden, Hogg-Johnson & Tannock, 2005). While ADHD is defined and diagnosed based on the presence of observed behavior, neuropsychological investigations suggest that impairments in executive function based in the frontal/prefrontal cortex may in part underlie the impairments seen in the majority of children with ADHD. Not all children with ADHD have executive dysfunction based on neuropsychological tests, and executive function impairments are not specific to ADHD as they also occur with ASD, learning disability, and depression (Diamond, 2013; Duff & Sulla, 2015; Vilgis, Silk, & Vance, 2015; Weyandt, 2005; Willcutt, Doyle, Nigg, Faraone, & Pennington, 2005). Other neurocognitive characteristics often seen in individuals with ADHD, such as slow processing speed and variability in reaction time, are also associated with symptoms and impairment (Jacobson et al., 2011; Pievsky & McGrath, 2017). Executive functions develop throughout childhood and adolescence, and their rapid development in adolescence may underlie improvements in ADHD in this age group (Satterthwaite et al., 2013).

Language impairments also commonly occur in children with ADHD (Sciberras et al., 2014), although rates vary widely from study to study (Redmond, 2016). Some children have deficits in the structural language components that are commonly tested when language concerns are suspected, such as vocabulary, phonology, semantics, and syntax. Pragmatic language deficits, however, which may not be routinely tested, are even more common and may exist when structural language is in the normal range for age (Green, Johnson, & Bretherton, 2014). Pragmatic deficits may underlie the social difficulties common in children and adolescents with ADHD (Leonard, Milich, & Lorch, 2011) and may include excessive talking, poor conversational turn-taking, and reduced organization of expressive language (i.e., starting in the middle of a narrative, not recognizing the background needed by the listener, poor sequencing of content, and excessive tangential explanation). Difficulty with verbal memory, listening comprehension, and organization of verbal output also occur in children with ADHD, even in the absence of specific language impairments (McInnes, Humphries, Hogg-Johnson, & Tannock, 2003). Impairments in auditory processing can also occur with symptoms of ADHD and contribute to academic underachievement (Dawes & Bishop, 2009).

Academic underachievement is a concern of many parents of school-age children with ADHD, even in the absence of criteria for a learning disability. Inattention, not hyperactivity/impulsivity, is predictive of poorer performance on academic measures (Semrud-Clikeman, 2012). Difficulty reading (most often in the form of

problems with fluency, comprehension, or engagement with—and retention of—written material) often occurs in students with ADHD (Friedman, Rapport, Raiker, Orban, & Eckrich, 2017b), even in the absence of a diagnosed reading disability (Ghelani, Sidhu, Jain, & Tannock, 2004; Willcutt, Pennington, Olson, Chabildas, & Hulslander, 2005). Other academic problems commonly seen in children with ADHD include math calculation and applied problem-solving and written expression (Friedman, Rapport, Orban, Eckrich, & Calub, 2017b; Molitor, Langberg, & Evans, 2016).

Problems with writing are especially common in children with ADHD; they are likely due to a combination of difficulties with fine motor control, visual motor integration, inefficiencies in working memory, and impairments of organization and planning. In a study of ADHD and written-language disorder (WLD), the cumulative incidence of written-language disorder in children with ADHD was 64.5% for boys and 57% for girls, compared with 16.5% for boys and 9.4% for girls without ADHD. For both boys and girls with ADHD, the risk of written-language disorder in the absence of a comorbid RD was similar, but interestingly, the risk for written-language disorder was increased for girls with ADHD and reading disability compared with boys with ADHD and reading disability (Yoshimasu et al., 2011).

Executive function impairments, particularly weak working memory, contribute independently from ADHD symptoms to academic difficulties. In fact, weak working memory is emerging as the primary factor related to academic impairment in children and adolescents with ADHD (Friedman et al., 2017b; Jacobson et al., 2011; Kasper, Alderson, & Hudec, 2012; Simone, Marks, Bedard, & Halperin, 2018). It is predictive of academic function, symptom persistence, and degree of impairment (Karalunas et al., 2017; Simone et al., 2018; Sjowall, Bohlin, Rydell, & Thorell, 2017; van Lieshout et al., 2017). Slow processing speed also contributes to academic deficits, best documented for reading skills, but it also has an impact on adaptive skills, anxiety, and social competence (Cook, Braaten, & Surman, 2017).

Many children with ADHD have social difficulties and face peer rejection, an important risk factor for later negative outcomes. Social skill deficits include disruptive and inappropriate social behaviors, deficient social cognition and social problem-solving, and poor emotional regulation (Gardner & Gerdes, 2015). They have difficulty “reading” the nuances of social behavior or inhibiting impulsive responses. They may react excessively or overly negatively to the behavior of others. Some children with ADHD have difficulty initiating or sustaining verbal turn-taking or other reciprocal aspects of peer relations, and they may find themselves passively or actively ignored and without the deeper

friendships that older school children begin to develop. They may be inflexible or perfectionistic, leading to “bossiness” with peers. Many children with ADHD tend to overestimate their social competency and don’t recognize and adjust their maladaptive behavior (Owens, Goldfine, Evangelista, Hoza, & Kaiser, 2007). As a result, their peers appear to recognize their differences and reject them within a very short time (Sibley, Evans, & Serpell, 2010). Other children with ADHD are acutely aware of their social differences, and their self-esteem suffers as a result. Peer difficulties persist even after reduction in symptoms of ADHD with stimulants or behavioral intervention (Gardner & Gerdes, 2015; Hoza, 2007; Nijmeijer et al., 2007). Peer difficulties are equally problematic in girls with ADHD (Kok, Groen, Fuermaier, & Tucha, 2016), even though they may not have the same rates of externalizing behavior symptoms. Peer rejection persists into adolescence and can lead to further negative outcomes (Mrug et al., 2012).

Sleep problems as well as specific sleep disorders are more common in children and adolescents with ADHD than in their peers (25%–55%; Bioulac, Micoulaud-Franchi, & Philip, 2015). These include behaviorally based insomnia, circadian rhythm disorders, sleep-disordered breathing, and sleep-related movement disorders, including restless leg syndrome/periodic limb movement disorder (Cortese et al., 2013; Tsai, Hsu, & Huang, 2016; see Chapter 28). Parents report more bedtime resistance, sleep-onset difficulty, night awakenings, difficulty with morning awakenings, and daytime sleepiness (Cortese, Faraone, Konofal, & Lecendreux, 2009). Objectively, polysomnograms and actigraphs show increased latency to sleep onset, decreased sleep efficiency, more sleep-stage shifts per hour, and a higher apnea-hypopnea index (Cortese et al., 2009) but not alterations in sleep architecture or REM sleep (Baglioni et al., 2016). Co-existing internalizing conditions, such as anxiety or depression, further increase the risk for sleep problems (Accardo et al., 2012). The relationship between sleep and ADHD is bidirectional—ADHD symptoms can worsen sleep quality and quantity, while reduced sleep quality and quantity can cause or exacerbate ADHD symptoms. The propensity for sleep problems in ADHD may be based on shared genetic and anatomical underpinnings. Genes related to catecholaminergic and circadian rhythms and the dorsolateral and ventrolateral prefrontal and dorsal anterior cingulate cortices have been implicated in both (Cortese et al., 2013). ADHD may contribute to sleep problems via an increased risk for poor sleep hygiene (i.e., difficulty with bedtime routines, use of electronics before bed, difficulty slowing down thoughts or body, and insomnia-related side effects of several medications for ADHD; Cortese

et al., 2013). Medications for ADHD have been shown to cause longer sleep latency, worse sleep efficiency, and shorter sleep duration (Kidwell, Van Dyk, Lundahl, & Nelson, 2015). Sleep disorders contribute to or cause ADHD symptoms via excessive daytime sleepiness, while treatment of sleep-disordered breathing with adeno-tonsillectomy may improve ADHD symptoms (Bioulac et al., 2015; Vélez-Galarra, Guillén-Grima, Crespo-Eguílaz, & Sánchez-Carpintero, 2016).

Children with ADHD also have an increased incidence of problems with motor coordination, which may impair written work in school and social participation in athletic activities (Martin, Piek, & Hay, 2006). Half of children with ADHD will also meet criteria for developmental coordination disorder (DCD), characterized by poor motor performance to a degree that causes functional impairment. Impairments in visual-spatial organization and cerebellar function are thought to be common underlying mechanisms for these two disorders (Piek & Dyck, 2004).

CAUSES OF ADHD

Genetics

The most common etiological factor in the development of ADHD is heredity. Siblings of children with ADHD are between five and seven times more likely to be diagnosed with ADHD than children from unaffected families. Each child of a parent with ADHD has a 25% chance of having ADHD (Faraone et al., 2005; Sharp, McQuillin, & Gurling, 2009). Between 55%–92% of identical twins will be concordant for ADHD, and heritability is estimated at 76% (Faraone et al., 2005). Genetic changes may be as small as single substitutions of one nucleotide in the coding or noncoding region of the DNA for a gene (single nucleotide polymorphisms [SNPs]) or somewhat larger copy number variants (CNVs), which are increased or decreased numbers of copies of a gene or part of a gene (see Chapter 1). Large duplications or deletions of genetic material that inactivate the protein product of a gene are referred to as mutations. A large number of single nucleotide polymorphisms and a small number of copy number variants have been associated with ADHD symptoms. Large mutations do not appear to cause ADHD in isolation, but they do cause genetic syndromes that may include ADHD symptoms as part of a larger clinical phenotype (i.e., fragile X syndrome or 22q deletion syndrome; see Chapters 1 and 15 and Appendix B).

Initially, the search for genetic causes of ADHD focused on specific genes that might be suspected to play a role based on their involvement in the dopamine and norepinephrine neurotransmitter systems.

Dopamine-related genes are candidate genes for investigating the basis for ADHD because evidence from multiple sources indicates that dopamine is involved in the modulation of attention and behavioral regulation in the frontal cortex and its connections, particularly the striatum (see Chapter 8). Norepinephrine is another neurotransmitter that plays an important role in orienting attention and regulating alertness in the frontal cortex and in other areas of the cortex and lower brain. Medications that are effective in ameliorating ADHD symptoms have consistently been shown to affect one or both of these neurotransmitters (Banaschewski, Becker, Scherag, Franke, & Coghill, 2010; Kieling, Goncalves, Tannock, & Castellanos, 2008). In molecular genetic studies of families (linkage analysis), specific **alleles** (common variants of a gene found in a given population) of particular candidate genes have been found to occur at higher frequencies in individuals who have ADHD than can be explained by chance alone. Different alleles tend to be present in those individuals within the family who do not have ADHD. This suggests that specific alleles of these genes may confer susceptibility to ADHD and can be used to identify genes that confer susceptibility to ADHD. More recently, genome-wide association studies (GWAS) have allowed detection of genetic changes associated with ADHD in locations throughout the entire genome, even when the gene at that location is not suspected or when the function of the particular gene in that location is unknown.

Multiple candidate genes, a large number of single nucleotide polymorphisms, and a small number of copy number variants have been associated with susceptibility to ADHD, including genes related to the dopamine, norepinephrine, serotonin, acetylcholine, gamma aminobutyric acid, and glutamate neurotransmitter systems, as well as genes associated with neuronal migration and plasticity, cell adhesion, neurotransmitter release and cell signaling, cell division, and neuroimmunology (Akutagawa-Martins, Rhode, & Hutz, 2016; Banaschewski et al., 2010), but none explain a substantial proportion of the risk for ADHD in all but a small number of families. Thus, researchers have begun to explore polygenic risk (the effect of having multiple susceptibility alleles) and pathway analysis (the effect of having multiple susceptibility alleles in a specific functional pathway in the brain). These studies are preliminary, but they support the concept that multiple genes are together involved in one or more of the processes listed above and therefore confer susceptibility to ADHD (Lima et al., 2016; Middeldorp et al., 2016; Mooney et al., 2016).

It has also been shown that there is overlap in the susceptibility genes based on single nucleotide polymorphism analysis across different neuropsychiatric and developmental disorders, with ADHD having

a statistically significant overlap with major depressive disorder (Cross-Disorder Group of the Psychiatric Genomics Consortium et al., 2013) and educational underattainment (Shadrin et al., 2018). Having a higher number of susceptibility genes has also been shown to increase the risk for the presence of co-existing conditions and persistence of ADHD symptoms over time (Riglin et al., 2016). In addition, **epigenetic** changes (see Chapter 1), such as increased methylation in genes related to the neurotransmitter systems, can influence the expression of ADHD symptoms. For example, in studies of identical (monozygotic) twins discordant for ADHD, increased methylation of the D4 subtype of the dopamine receptor, rather than single nucleotide polymorphisms or copy number variants, predicted ADHD symptoms (Chen et al., 2018; Dadds, Schollar-Root, Lenroot, & Moul, 2016).

Other Etiologic Factors

Although the most common etiology of ADHD is genetic, other conditions known to affect brain development may result in ADHD symptoms or increase the risk of those genetically at risk for the disorder. These can be grouped into five general categories: 1) specific genetic syndromes, 2) prenatal exposure to toxins, 3) prenatal exposure to maternal metabolic conditions, 4) hypoxia-ischemia, and 5) medical conditions. Rather than directly “causing” ADHD, these risk factors are likely to affect the neuropsychological processes such as memory, temporal processing, response variability, and executive function skills that lead to symptoms of this diagnosis (Seo et al., 2015; Wiggs, Elmore, Nigg, & Nikolas, 2016). These factors increase the risk for other developmental disorders as well, such as autism and decreased IQ. Most studies typically indicate an “association” rather than prove a “cause,” and most do not control for all possible associated factors. For example, prematurity may be associated with a higher risk for ADHD via an increased risk for hypoxia-ischemia rather than from the prematurity itself (Sciberras, Mulraney, Silva, & Coghill, 2017).

Genetic syndromes in which ADHD is more common than in the general population include sex chromosome abnormalities (Klinefelter syndrome, Turner syndrome, and fragile X syndrome) and other syndromes that may be inherited or genetic (e.g., neurofibromatosis type 1, Williams syndrome, and the 22q11 deletion syndrome; see Appendix B; reviewed by Lo-Castro, D’Agati, & Curatolo, 2010). Toxins linked to ADHD include prenatal exposures to cigarette smoking, lead (even at low levels; Ha et al., 2009; Nicolescu et al., 2010; Seo et al., 2015; see Chapter 2), alcohol, cocaine, antidepressants (Figueroa, 2010), long-term

exposure to acetaminophen (Ystrom et al., 2017), and pesticides (reviewed in Mostafalou & Abdollahi, 2017). Maternal metabolic conditions that are associated with higher rates of ADHD include maternal thyroid disease (reviewed in Fetene, Betts, & Alati, 2017) and possibly maternal high fat diet/obesity (reviewed in Sullivan, Nousen, & Chamiau, 2014). In children with ADHD who do not have a family history, there is an increased incidence of complications during labor, delivery, and infancy (Sprich-Buckminster, Biederman, Milberger, Faraone, & Lehman, 1993). Pregnancy, labor, delivery and perinatal complications, prematurity, and low birth weight have been associated with an increased risk for ADHD in some studies, likely via the shared factor of prenatal or perinatal hypoxia-ischemia (Sciberras et al., 2017; Smith, Schmidt-Kastner, McGeary, Kaczorowski, & Knopik, 2016). Children who undergo surgery for congenital heart disease have alterations in cerebral blood flow, both prenatally and in association with the surgical intervention, and they have a higher risk for subsequent attention problems (Shillingford et al., 2009). Medical conditions associated with a higher risk for ADHD include prenatal and perinatal infection; traumatic brain injury (Chapman et al., 2010; Yeates et al., 2005); nutrient deficiencies such as iron, magnesium, zinc, and vitamin D (Villagomez & Ramtekkar, 2014; reviewed in Wang, Huang, Zhang, Qu, & Mu, 2017); and atopic (allergic) disease (Schans, Cicek, de Vries, Hak, & Hoekstra, 2017).

Structural and Functional Differences in the Brain

Multiple lines of evidence suggest that structural and functional differences exist in the brains of individuals with ADHD. The original study showing widespread differences in brain function, particularly in the prefrontal cortex, was done in adults with childhood-onset ADHD using positron emission tomography (PET) scanning (Zametkin et al., 1990; see Chapter 8). PET scans require the systemic injection of radioactive tracers to label neuronal activity and thus are difficult to justify for routine or repeated use in children. In contrast, magnetic resonance imaging (MRI), which uses a magnetic field and radiowaves to delineate brain structure, is considered safe and noninvasive; many studies of ADHD have used this technology. Volumetric MRI scans have shown important differences in the shape, thickness, and volume of specific brain areas compared with controls in many studies. Six regions have shown consistent differences: 1) the frontal lobes (including the dorsolateral prefrontal cortex and dorsal anterior cingulate cortex), 2) the inferior parietal cortex, 3) the

basal ganglia (particularly the right striatum), 4) the corpus callosum (particularly anteriorly), 5) the cerebellum, and 6) the parieto-temporal regions (reviewed in Friedman & Rapoport, 2015; Frodl & Skokauskas, 2012; Mahone et al., 2011; Wyciszkievicz, Pawlak, & Krawiec, 2017). Studies of the amygdala and hippocampus, part of the limbic system, have also shown anomalies in shape and volume in children with ADHD (Hoogman et al., 2017). Networks in the frontal cortex serve as the “executive center,” processing incoming stimuli; connecting to other structures; and coordinating appropriate cognitive, emotional, and motor responses. The cerebellum and basal ganglia are thought to be involved because these areas are critical to motor planning, behavioral inhibition, and motivation. The hippocampus is involved in memory and the amygdala in facial and emotional processing. When compared with controls, these regions are 3%–4% smaller in subjects with ADHD and involve both gray and white matter, and these differences are present early in childhood (Shaw & Rabin, 2009). Longitudinal studies have shown delays in cortical maturation patterns in children with ADHD, resulting in reduced cortical thickness for age (particularly in the prefrontal cortex). Typically, after reaching maximal thickness at 10–14 years of age, a normal process of cortical thinning occurs into young adulthood (Giedd, Raznahan, Alexander-Bloch, Schmitt, Gotay, & Rapoport, 2015). In individuals with remitting ADHD, cortical thinning is reduced, ultimately resulting in cortical thickness similar to controls. Individuals in whom ADHD persists do not show a reduction in the degree of cortical thinning, resulting in a thinner cortex in adulthood (Shaw et al., 2013). Similar longitudinal developmental differences are found in the basal ganglia of children with ADHD (Shaw et al., 2014).

Functional MRI (fMRI) is a noninvasive MRI technique that measures variations in regional oxygen uptake in the brain, which correlates with cellular activity. fMRI studies indicate that subjects with ADHD have hypoactivation of the prefrontal cortex, parietal cortex, cerebellum, and caudate nucleus and that stimulant medication can increase activation in these areas (Casey, Nigg, & Durston, 2007). fMRI also allows detection of networks of brain regions that are activated simultaneously, either at rest or during performance of a task. The default mode network is a group of connected brain regions that become active or inactive simultaneously. This network includes the medial prefrontal, posterior cingulate/precuneus, and temporoparietal cortical areas. The default mode network is active when the brain is “at rest” and must be suppressed in order to initiate a cognitively demanding task. The cognitive control or executive network (including dorsolateral prefrontal, anterior cingulate, anterior insular,

supplementary motor, and posterior parietal cortical areas) is activated for demanding cognitive tasks such as using working memory, inhibiting behavior, and cognitive shifting (see Chapter 8 for further information regarding the anatomy and structural organization of the brain). Studies suggest that the default mode network is more strongly connected in children and adults with ADHD, which may make it more difficult to suppress in order to initiate cognitively demanding tasks (Metin et al., 2015; Mohan et al., 2016).

Diffusion-weighted (DW) MRI uses the diffusion of water molecules to illuminate tissue microarchitecture. A specific type of DW-MRI called diffusion tensor imaging is particularly useful for mapping white matter tracts in the brain (see Chapter 8). Studies in children, adolescents, and adults with ADHD have shown differences in white matter tracts connecting fronto-striatal-cerebellar regions, posterior brain regions, and right and left hemispheres (Chen et al., 2016; Tamm, Barnea-Goraly, & Reiss, 2012; Yoncheva et al., 2016). This technique also suggests that ADHD combined and inattentive presentations may have different white matter connectivity characteristics (Ercan et al., 2016; Svatkova et al., 2016). As with volumetric findings, those with persistent ADHD have been shown to have more prominent white matter tract anomalies (Friedman & Rapoport, 2015). Furthermore, differences in white matter microarchitecture have been shown to be inherited (Sudre et al., 2017), providing a link among symptoms, genetics, and brain structure.

Structural and functional imaging scans show convergent findings about the networks of brain regions that function differently in individuals with ADHD across the age spectrum. While they are not yet sufficiently specific to be used diagnostically, this can be anticipated in the not-too-distant future.

THE EVALUATION PROCESS

Evaluating a child for ADHD requires assessment of 1) symptoms of ADHD; 2) different conditions that might cause the same symptoms; 3) coexisting conditions; and 4) any associated medical, psychosocial, or learning issues that may not reach the threshold for a specific diagnosis but may nonetheless influence the treatment plan. In order to cover these four areas, a comprehensive history, physical/neurological examination, and academic assessment must be completed. Findings in these examinations may prompt additional investigations, including consultation from specialists.

The history, generally taken from the parents, with the child's participation depending on age, includes current status and concerns, previous treatments and their effects, prenatal and perinatal events, medical history,

developmental, psychiatric and behavioral history, educational course, social and family circumstances, and biological family history for ADHD symptoms and associated disorders. The main pediatric and child psychiatric professional organizations—the American Academy of Pediatrics (AAP) and the American Academy of Child and Adolescent Psychiatry (AACAP)—provide guidelines for the assessment of ADHD, and they both emphasize the importance of adhering to the *DSM* diagnostic criteria. Information from teachers, typically in the form of standardized rating scales, should be included to document impairment in the school setting (AACAP, 2007; AAP, 2011). The medical examination should focus on growth parameters and physical signs of sensory, genetic, chronic medical, and neurologic disorders, as well as mental status, informal communicative ability and insight, and motor skills.

Educational testing (including intellectual, achievement, and processing measures) will be necessary for many children, and it should focus on the careful assessment for learning disabilities, memory and processing problems, and areas of academic weakness that may not meet criteria for a learning disability (see Chapters 13 and 20). Additional support may allow the child to make better academic progress rather than falling further behind. This should include assessments of reading mechanics and comprehension, spelling, mathematical concepts and computation, and writing. Tests of verbal and visual memory and processing efficiency can be useful in identifying reasons for intellectual achievement discrepancies and can inform choices about educational remediation strategies.

Standardized interview formats and rating scales for parents and teachers collect information about symptoms of ADHD and related conditions, comparing the level of symptoms to age- and gender-matched peers, and they assess the level of functional impairment. In addition, rating scales designed for teachers allow the required collection of information from more than one setting. Commonly used rating scales to assess *DSM* ADHD symptoms include the ADHD Rating Scale-5 for Children and Adolescents (DuPaul, Power, Anastopoulos, & Reid, 2016), the Conners-3 Rating Scales (Conners, 2008), the Swanson, Nolan and Pelham (SNAP) rating scale (Swanson et al., 2012), and the Vanderbilt Rating Scale (Collett, Ohan, & Myers, 2003; Pelham et al., 2005; Wolraich et al., 2003).

Structured diagnostic interviews are quite time-consuming and require training for standardized administration; therefore, they are most often used in psychiatric and research settings. Commonly used structured diagnostic interviews include the Diagnostic Interview Schedule for Children (Shaffer Fisher, Lucas, Dulcan, & Schwab-Stone, 2000) and the Kiddie

Schedule for Affective Disorders and Schizophrenia (K-SADS; Kaufman et al., 1997). These allow the exploration of other diagnoses that may be the cause of the child's symptoms or may co-exist with ADHD (Leffler, Riebel, & Hughes, 2015). Broad rating scales, such as the Child Behavior Checklist and Teacher Report Form (Achenbach & Rescorla, 2001) or the Behavior Assessment System for Children (Reynolds & Kamphaus, 2015), may also be used for this purpose (Collett et al., 2003; Pelham et al., 2005).

Because comprehensive information is required, several professionals are typically involved (e.g., physician, psychologist, and teacher). The primary person responsible for formulating the diagnosis and communicating the findings and recommendations to the family must be experienced with the range of coexisting conditions and associated impairments. This person is typically a physician (pediatrician, neurodevelopmental or developmental-behavioral pediatrician, or a neurologist or psychiatrist) or psychologist. Additional professionals, such as speech-language pathologists, occupational therapists, and learning specialists, may be asked to provide input (see Box 19.1). While such a complex evaluation can be coordinated through a primary care setting, there are also a number of barriers related to knowledge, time, resources, and medical/mental health insurance coverage that limit access to

a thorough evaluation for many children (Rushton, Fant, & Clark, 2004).

TREATMENT OF ADHD

Most treatment plans for ADHD will include education about the disorder and one or more of the following interventions: behavioral and family counseling, educational interventions, and medication. Often a combination of treatments is used because of the chronicity and multiple types of impairment caused by ADHD (AAP, 2011).

Education About ADHD and Emotional Support for Families

Parents and older children need to learn as much as possible about ADHD to allow them to be effective decision makers and advocates. The clinician can provide some information directly but should also guide the family toward resources such as national support and advocacy organizations, books and online resources, and parent support groups. Growing up with or parenting a child with ADHD can be a significant challenge. Parents and children will need emotional support to perform the difficult work needed to address the symptoms and consequences of ADHD.

BOX 19.1 INTERDISCIPLINARY CARE

The ADHD Team

Physician evaluators of children with attention-deficit/hyperactivity disorder (ADHD) may be primary pediatricians, developmental and behavioral pediatricians, pediatric neurologists, or child and adolescent psychiatrists. Psychologists may also evaluate, diagnose, and make treatment recommendations for children with ADHD. Additional team members who provide invaluable input for diagnosis and treatment include the following:

- The school psychologist is the school team leader who may perform a comprehensive psychoeducational evaluation to determine a student's eligibility for special education services, develop an individualized education program (IEP) if needed, or serve as team leader in developing a Chapter 15/Section 504 accommodation plan if needed in the absence of an IEP.
- The student's teacher is the school team member who will have direct experience with the student's strengths and weaknesses and who may be the first to recognize a student's need for additional intervention in the academic environment. The teacher may have implemented modifications informally and will have knowledge of what has and has not been helpful.
- The speech-language pathologist, occupational therapist, and physical therapist may be involved in the evaluation and treatment of children with language, speech, and fine and gross motor difficulties, respectively, in order to reduce the chance that these impairments will further affect a child's ability to attend to, and complete, tasks that require these skills in school and community settings.
- The behavior specialist may work with other team members to develop a positively oriented behavior support plan.

Behavioral Counseling and Social Skill Intervention

Behavior therapy is the type of counseling intervention with the best documented efficacy in preschoolers (Greenhill et al., 2008; Murray, 2010) and school-age children (DuPaul, Gormley, & Laracy, 2014) with ADHD, especially if there are additional disruptive behaviors (Coates, Taylor, & Sayal, 2015; Eyberg, Nelson, & Boggs, 2008). It involves training parents and teachers in the principles of behavior management that are adapted for a particular child in a particular setting. Behavior therapy changes behavior by altering the antecedents to, or consequences of, the behavior in such a way that it increases the chances that the child will successfully engage in the desired behaviors and reduces the chances that the child will engage in unwanted behaviors (see Chapter 34). Studies also suggest efficacy of behavior therapy in adolescents with ADHD, though there are limited data, and additional psychosocial interventions are more often necessary in this age group (Robin, 2008; Young & Amarasinghe, 2010). Parent/teacher training can also improve parenting skills and the adult-child relationship as well as decrease subsequent child conduct problems (Daley et al., 2014; Williford & Shelton, 2014).

Behavior therapy can be done in individual or group sessions and forms the basis for most parent training and classroom management programs for children with ADHD. Studies have consistently found that these interventions result in at least short-term improvements in the behavior (Pelham & Fabiano, 2008; Young & Amarasinghe, 2010) and homework problems (Langberg et al., 2010) of children with ADHD. A study of a very intensive behavioral intervention that also included social skill building and emotional support found some persistent benefit from this intervention 15 months after the intervention ended (MTA Cooperative Group, 2004a); however, this level of treatment intensity is unlikely to be widely available (Young & Amarasinghe, 2010). Factors that may interfere with successful parent training in behavior management include parental depression or ADHD, high levels of marital discord (Chronis, Chacko, Fabiano, Wymbs, & Pelham, 2004), low maternal parental self-efficacy, and multiple coexisting conditions in the child (van den Hoofdakker et al., 2010). Behavior therapy is the first line of treatment in preschoolers with ADHD, whereas medication treatment with behavior therapy is generally recommended in school-age children (AAP, 2011; Council on Early Childhood, Committee on Psychosocial Aspects of Child and Family Health, and Section on Developmental and Behavioral Pediatrics, 2016).

There is insufficient evidence to recommend family therapy as a specific treatment for core ADHD symptoms (Bjornstad & Montgomery, 2005); however, disruptive behavior can lead to increasingly negative and coercive patterns of parent-child interaction (Deault, 2010). There is some evidence for its effectiveness for families with a defiant adolescent (Robin, 2014). Family therapy can help to mitigate the effects of parenting a child with ADHD on the marital relationship and sibling interactions. It also may be necessary when parents cannot agree on an intervention plan or other family stressors interfere with implementation of a treatment plan.

Cognitive behavioral therapy (CBT) changes behavior by helping individuals to change self-defeating thought and behavior patterns. It is a well-documented treatment for depression and anxiety and has recently been shown to be effective in the treatment of ADHD in adults (Safren et al., 2010; Solanto et al., 2010; Young & Amarasinghe, 2010) and adolescents (Modesto-Lowe, Charbonneau, & Farahmand, 2017). Preliminary evidence in adults with ADHD suggests that CBT may actually enhance white matter connectivity in frontoparietal and cerebellar networks (Wang et al., 2016). Individual psychotherapy or play therapy may be helpful for children with coexisting mood, anxiety, or self-esteem problems but is not effective in treating the core symptoms of ADHD (Barkley, 2004).

Coaching is an emerging approach to improve the daily functioning of (typically) older teens and adults with ADHD, but there is little empiric research support at this time (Prevatt, 2016). It involves regular meetings between the individual with ADHD and his or her coach to identify executive function impairments leading to problems in daily functioning and to develop systems and strategies to address them. Coaching is most likely to be successful when the individual recognizes the problems and wishes to address them but cannot seem to do it without help. It does not address core symptoms of ADHD, coexisting conditions, or motivational or emotional problems. Coaches are typically psychologists, educators, social workers, or successful adults with ADHD. A positive step in the field has been the development of professional standards and certification procedures (Murphy, Ratey, Maynard, Sussman, & Wright, 2010). Coaching is often done online, allowing access to individuals who may not live near a coach.

Interpersonal difficulties, such as peer victimization (bullying) and social isolation, are common in individuals with ADHD (Hoza, 2007; Nijmeijer et al., 2007) and may result, in part, from the social skill deficits described earlier in this chapter; thus, social skill interventions may be recommended as part of a

comprehensive treatment plan. Social skill groups are often conducted in school or other group settings and teach by modeling, practicing, and reinforcing pro-social behaviors. When social skills interventions for children with ADHD are evaluated as a single intervention, however, the results have generally been disappointing (Abikoff et al., 2004; Barkley, 2004; Storebø et al., 2011). It seems that children “know” or can be taught appropriate skills but then do not apply them when needed. The social skills interventions that seem to be the most effective are intensive, sustained, and conducted in naturalistic settings (i.e., at a camp or school, rather than in a clinic) and are combined with parent training in behavior reinforcement (Mikami, Jia, & Jiwon, 2014; Pelham & Fabiano, 2008). See Box 19.2 for more information on the efficacy of behavioral interventions.

Educational Treatment

Behavioral treatments, such as token reinforcement systems, differential teacher attention, daily behavior report cards, and environmental modifications (e.g., preferential seating), are important in the school setting for supporting students with ADHD. However, it has become apparent that these students are at risk for underachievement even when attention is managed with medication or behavior therapy. Interventions aimed at improving study skills, organization, planning, memory and use of memory strategies, and homework completion are often needed, whether provided in a tutoring setting or as part of a school-based educational program (DuPaul, Gormley, & Laracy, 2014). These interventions are particularly relevant

in middle school and high school, as the increased demand for executive and study skills can be overwhelming for students with deficits in these areas. While typical students may develop these skills spontaneously as work demands increase, the student with ADHD typically requires both explicit teaching of the skills and behavioral reinforcement for implementing them over extended periods of time (Evans, Langberg, Egan, & Molitor, 2014).

Appropriate school programs are extremely important for children with ADHD, many of whom have coexisting learning disabilities. When children with ADHD are in need of more assistance than is typically provided in the classroom, they may qualify for modification within their general education classes or in special education settings under either Section 504 of the Rehabilitation Act of 1973 (PL 93-112, Section 504) or the Individuals with Disabilities Education Improvement Act of 2004 (IDEA, 2004; PL 108-446); Chapter 33).

A child with ADHD who needs modification of curricular materials, demands, or teaching methods should have an individualized education program (IEP; see sites.ed.gov/idea/). Although ADHD is not one of the disabilities specifically included under IDEA, some children with ADHD will have an IEP under a coexisting condition such as specific learning disability, speech-language impairment, or emotional disturbance. Others will be provided an IEP under the IDEA category of “Other Health Impaired.” When a learning disability is present, specific intervention for the learning disability as well as intervention for ADHD are recommended, and this will require an IEP.

A child with ADHD who is less educationally impaired by his or her symptoms may still be eligible

BOX 19.2 EVIDENCE-BASED PRACTICE

Sequencing Medication and Behavioral Interventions for ADHD

In a study of 146 children with attention-deficit/hyperactivity disorder (ADHD), subjects (ages 5–12, 76% male) were randomized to receive a “low dose” of behavioral intervention or extended-release medication. After a minimum of 8 weeks of treatment, insufficient responders were randomized to either a “higher dose” of the same treatment or the other treatment. They were treated and assessed for 1 school year. Those who analyzed the results were blinded. Parents, teachers, and those who provided the treatment and collected data were not. The primary outcome measure was classroom rule violations; secondary outcomes included out-of-class disciplinary events and parent and teacher ratings of disruptive and social behavior. Although a higher percentage of children beginning with behavioral treatment required medication than the reverse (67% vs. 47%), behavioral treatment first resulted in better primary and secondary outcome scores and lower medication dose at the end of the study, as well as better parent attendance at the behavior treatment sessions (Pelham et al., 2016).

for accommodations through a “Section 504 Plan” (www2.ed.gov/about/offices/list/ocr/504faq.html). Accommodations allow the child with ADHD to successfully “access” the regular education environment. These may include (but are not limited to) 1) regular home–school communication; 2) a behavior program to support desired behaviors; 3) a plan to ensure that the student understands and is following through on instructions; 4) modifications of testing time, format, or environment; 5) visual supports for verbal information; 6) an extra set of materials at home; and 7) technological assistance, such as the use of recording devices, recorded books, and a laptop for typing and speech-to-print applications.

Pharmacological Treatment

Stimulant medications are the most effective and commonly prescribed medications for ADHD. Atomoxetine, sustained-release guanfacine, and sustained-release clonidine are the only nonstimulant medications approved by the U.S. Food and Drug Administration (FDA) for the treatment of ADHD. Non-FDA-approved medications that have been used to treat ADHD include antidepressants (bupropion and tricyclics) and immediate-release or short-acting guanfacine and clonidine. There is emerging evidence that combination therapy with extended-release guanfacine and stimulant medication can be helpful in children with suboptimal response to monotherapy (Childress, 2012; McCracken et al., 2016). See Chapter 38 and Appendix C for information on medication formulations, dosages, and side effects.

Stimulant Medication Stimulant medications, including methylphenidate and amphetamine (see Table 19.2), have been used for the treatment of children with disruptive behaviors for over 70 years and have been more frequently used and more thoroughly studied than any other psychopharmacologic treatment in children. According to data collected from the National Survey on Children’s Health in the United States, approximately 70% of children diagnosed with ADHD take medication, with 3.5 million children being treated overall (Visser et al., 2015). Stimulants are statistically more effective than nonstimulant options (Coghill et al., 2017) and appear to work equally well regardless of gender or *DSM* subtype, with treatment initiated more in boys and for combined or hyperactive/impulsive subtypes (Barbarelli et al., 2014). Preschoolers appear to have a somewhat less beneficial-effect/side-effect ratio than older children (see later section titled Stimulants in Preschoolers). There is some evidence

that pharmacogenomics may aid in treatment decision making as studies show that dose response of stimulants (Stein et al., 2014) as well as side effects are linked to neuroreceptor genotype (Levy, Wimalaweera, Moul, Brennan, & Dadds, 2013). Various pharmacogenetic testing kits are available, but there is limited evidence for their clinical value.

Beneficial Effects Stimulant medications significantly reduce symptoms in 70%–90% of children and adolescents correctly diagnosed with ADHD (Wigal, 2009). They result in a rapid and often dramatic improvement in attention and distractibility and a decrease in impulsivity and hyperactivity. In addition, they improve academic productivity and accuracy, improve parent–child interactions, and decrease aggression. Teacher ratings of behavior, as well as the child’s quality of life, improve with stimulant treatment (Punja et al., 2016; Storebø et al., 2015), and stimulants improve driving performance in adolescents and young adults with ADHD (Gobbo & Louzã, 2014). Stimulants may also have positive effects on academic achievement (Lu et al., 2017), although these are modest compared with their effects on behavior, indicating that additional interventions are needed in these areas (Jitendra, DuPaul, Someki, & Tresco, 2008; MTA Cooperative Group, 2004a, 2004b; Raggi & Chronis, 2006). The positive effects of stimulants on executive function appear to be in the areas of attention and response inhibition (Pauls et al., 2012) as well as working memory, reaction time, and variability (Coghill et al., 2014). Children with more severe executive function impairments show an increased response to stimulant treatment of ADHD symptoms (Hale et al., 2011; Kubas, Backenson, Wilcox, Piercy & Hale, 2012). Stimulants have “normalizing” effects on biological parameters that differentiate individuals with ADHD from their peers including activation patterns in the frontal cortex using fMRI (Rubia, Alegria, & Brinson, 2014), cortical-striatal-cerebellar attentional networks, basal ganglia surface morphology, and event-related brain (electrical) potentials (Bush et al., 2008; Ozdag, Yorbik, Ulas, Hamamcioglu, & Vural, 2004; Rubia et al., 2011; Sobel et al., 2010).

However, although beneficial effects on behavior have been very clearly demonstrated in short- to intermediate-term studies, long-term studies show no significant long-term reduction in symptoms (Swanson et al., 2017). It should also be noted that response to stimulant treatment is not diagnostic of ADHD, since individuals with other psychiatric or developmental disorders, and even individuals with typical development and mental health, display similar effects when given stimulant medication (Rapaport et al., 1978).

Table 19.2. Stimulant medications commonly used to treat attention-deficit/hyperactivity disorder

Brand name	Generic name of active medication	Usual duration of action (hours)	Dosages available (milligrams)	Other
Ritalin	D,L-methylphenidate	3–4	Tablets–5, 10, 20	
Focalin	D-methylphenidate	3–4	Tablets–2.5, 5, 10	Contains only the active isomer of methylphenidate; typical dose is half that of D,L-methylphenidate
Focalin XR	D-methylphenidate	8–12 (12 for 20-mg dose)	Capsules–5, 10, 20, 30	Capsule can be opened and sprinkled
Methylin	D,L-methylphenidate	3–4	Tablets–2.5, 5, 10 Suspension–5 mg/5 ml and 10 mg/5 ml	Tablets are grape flavored and chewable
Metadate CD	D,L-methylphenidate	6–8	Capsules–10, 20, 30, 40, 50, 60	Capsule can be opened and sprinkled; 30% of dose immediately released
Ritalin LA	D,L-methylphenidate	6–8	Capsules–10, 20, 30, 40, 50, 60	Capsule can be opened and sprinkled; 50% of dose immediately released
Concerta	D,L-methylphenidate	10–12	Capsule–18, 27, 36, 54	Must be swallowed whole; 22% of dose immediately released
Daytrana	D,L-methylphenidate	Up to 12	Patch–10, 15, 20, 30	Duration depends on timing of removal
Aptensio XR	D,L-methylphenidate	8–10	Capsule – 10, 15, 20, 30, 40, 50, 60	40% released immediately; capsule can be opened and sprinkled
Quillivant XR	D,L-methylphenidate	10–12	Oral suspension–25 mg/5 mL	20% immediate release
Quillichew ER	D,L-methylphenidate	6–8	chewable tablet–20, 30, 40	20% immediate release
Cotempla XR	D,L-methylphenidate	8–10	Orally disintegrating tablet–8.6, 17.3, 25.9	25% immediate release
Dexedrine	Dextroamphetamine	3–6	Tablet–5	
Dexedrine Spansules	Dextroamphetamine	6–8	Capsule–5, 10, 15	
Adderall	Mixed salts of amphetamine	3–6	Tablets–5, 7.5, 10, 12.5, 15, 20, 30	
Adderall XR	Mixed salts of amphetamine	8–10	Capsule–5, 10, 15, 20, 25, 30	Capsule can be opened and sprinkled; 50% of dose immediately released
Vyvanse	Lisdexamfetamine	12	Capsule–20, 30, 40, 50, 60, 70	Inactive until lysine cleaved from amphetamine in the gastrointestinal tract
Dynavel XR	D,L-amphetamine	10–12	Oral suspension–2.5-mg amphetamine base/mL	Each mL is the equivalent of 4 mg amphetamine salt
Procentra	Dextroamphetamine sulfate	4–6	Oral solution 5 mg/5 mL	Immediate release, bubble gum flavoring
Zenzedi	Dextroamphetamine sulfate	3–6	Tablet–2.5, 5, 7.5, 10, 15, 20, 30	Immediate release
Evekeo	D,L-amphetamine	4–6	Tablet–5, 10	BID dosing; immediate release
Adzensys XR	D,L-amphetamine	6–8	Tablet–3.1, 6.3, 9.4, 12.5, 15.7, 18.8	Orally disintegrating tablet; 50% immediate release and 50% extended release
Mydayis	Mixed salts of amphetamine	12–16	Capsule–12.5, 25, 37.5, 50	Extended release; approved for age 13 and older only

Formulations Methylphenidate and amphetamine come in a variety of formulations (see Table 19.2). The beneficial effects and side effects of these two types of stimulants are nearly identical, although 30%–40% of children may respond better to one medication than the other (May & Kratochvil, 2010). A few meta-analyses indicate that amphetamine may improve symptoms

to a slightly greater degree than methylphenidate, but these studies did not take tolerability into account (Faraone & Buitelaar, 2010; Stueck, Munda, Svab, & Locatelli, 2015). Amphetamine-based stimulants are typically given at one half to two thirds the dose of the methylphenidate-based stimulants to account for differences in the potency of the two medications. Likewise,

dex-methylphenidate, the isolated, more effective d-isomer, has approximately twice the potency of d,l-methylphenidate and is given at approximately half the dose. Lisdexamfetamine is the only prodrug formulation, requiring cleavage of the attached lysine by gastrointestinal enzymes for activation.

The onset of action of immediate-release forms of methylphenidate and amphetamine is usually within 30 minutes of taking the dose. Based on the technology used to extend the duration of release, different formulations vary in how much of the medication is released immediately and time to onset, how the remainder is released (in a later bolus versus continuously), and duration of effect. Although Table 19.2 gives the typical duration of effect for the various formulations, there is significant variation among individuals. The methylphenidate patch is the only formulation that gives individuals the capacity to vary the duration of action on a daily basis (up to 10 hours) based on the timing of patch removal (Noven Therapeutics, LLC—<http://www.daytrana.com/>). There have been studies looking at the comparative efficacy of stimulants; however, the methods used for direct comparison of these studies have been inconsistent. The efficacy of stimulants varies based on pharmacokinetics and desired timing of positive effects; therefore, the formulation should be based on the needs of the individual (Coghill et al., 2013). For example, stimulants that release 50% of medication immediately (e.g., Ritalin LA, Focalin XR) seem to be more effective in the first four hours of treatment than OROS methylphenidate (e.g., Concerta), which is 33% immediate release.

Side Effects The most common adverse effects of stimulants are decreased appetite, headaches, stomachaches, growth, and sleep problems (Clavenna & Bonati, 2017; May & Kratochvil, 2010). As headaches, stomachaches, and sleep problems are common in untreated children with ADHD, it is important to determine the nature and frequency of these symptoms prior to starting the medication. The relationship of ADHD with sleep disturbances is explored in detail earlier in this chapter. There is an association with long-acting methylphenidate and sleep problems (Kidwell et al., 2015) with mixed results, as preexisting sleep problems show some improvement on higher doses (Becker, Froehlich, & Epstein, 2016).

Decreased appetite, weight loss, and abdominal pain are the most commonly reported gastrointestinal adverse effects in children (Holmskov et al., 2017). Decreased appetite is the most common adverse effect, but it is typically limited to lunchtime hours, with compensation at breakfast and dinner. Fewer children

have more extensive appetite suppression and weight loss. These children may benefit from caloric and nutrient supplementation to prevent weight loss and maintain adequate nutrition, or they may be able to eat in between doses of shorter-acting formulations. Appetite suppression and abdominal pain will prevent some children from tolerating stimulants; however, this common adverse effect may be relieved by adjusting the dose or changing stimulant type (Wolraich, McGuinn, & Doffing, 2007). It may be that the minority of children who experience abdominal discomfort have an underlying gastrointestinal condition that renders them prone to related side effects, such as gastroesophageal reflux, gastritis, or other inflammatory conditions. Treatment of the underlying condition may then allow such children to tolerate pharmacologic treatment for ADHD.

Less common, but potentially more problematic side effects include “rebound” effects, tics, and social withdrawal. *Rebound* refers to a temporary worsening of symptoms, including irritability, increased activity, or mood swings, when the medication wears off. Although it is estimated that 30% of school-age children experience some rebound effects, they are significant enough to require altering the medication regimen in only about 10% of cases (Carlson & Kelly, 2003). Preliminary results suggest that some young adults may have increased driving errors during rebound (Cox et al., 2008). Some children do become withdrawn on stimulant medication. This may improve with dose adjustment or switching to another medication. The best ways to mitigate medication side effects is an area that has not been systematically researched and is typically based on common clinical experience rather than scientific evidence.

Tics have been reported to occur in approximately 10% of children treated with stimulants (Lipkin, Goldstein, & Adesman, 1994), but they have also been reported in a similar percentage of community control samples (22% of preschoolers, 8% of elementary school children, and 3.4% of adolescents; Gadow & Sverd, 2006). Early reports suggested that stimulants induced or exacerbated tics (Gadow & Sverd, 2006; Palumbo, Spencer, Lynch, CoChien, & Faraone, 2004), but recent meta-analyses indicate that this is less common than originally thought (Cohen et al., 2015; Pringsheim & Steeves, 2011). In addition, tics that appear to be stimulant induced or exacerbated usually subside with time, after the dose is reduced, or when treatment is discontinued. In rare cases, tics that appear to have been induced by stimulants do not resolve or may even worsen over time. Given that tics and ADHD commonly co-occur (Denckla, 2006; Gadow & Sverd, 2006),

it is possible that those individuals whose tics appear to be induced by stimulants have a biological predisposition to develop tics. Clonidine, guanfacine, and atomoxetine (discussed below) can be alternative treatments in this population (Pringsheim & Steeves, 2011; Rizzo, Gulisano, Cali, & Curatolo, 2013).

Growth velocity slows by approximately 1.2 centimeters per year on average in prepubertal children during at least the first 2 years of continuous treatment with stimulants (MTA Cooperative Group, 2004b). In one study by Swanson and colleagues (2006), in preschoolers growth was 20% less and weight gain 55% less than expected over the first year of treatment. However, when school-age children were followed for up to 3 years, the slowed growth rates tended to stabilize, although growth rebound did not occur (Swanson et al., 2007).

Adult research suggests that stimulants can trigger activation of mania or psychosis in individuals with comorbid bipolar disorder if untreated (Viktorin et al., 2017). Research on children is limited in this area. Cardiovascular side effects secondary to sympathomimetic effects are more commonly part of anticipatory guidance with medication treatment of ADHD in pediatric use. Recent studies show no significant difference in QTc interval (an increased QTc interval on an electrocardiogram has been associated with increased risk of cardiac arrhythmias; Lamberti et al., 2015) with stimulant use, although an increase in pulse (heart rate) and blood pressure is still significant (Hennissen et al., 2017; Vitiello et al., 2012). In children without underlying cardiac abnormalities, recent research is conflicting, with some studies suggesting that cardiac adverse effects are rare and not associated with stimulant use (Olsson et al., 2012; Shin, Roughead, Park, & Pratt, 2016), while others suggesting an increase in adverse effects with stimulant use (Dalsgaard, Primdal Kvist, Leckman, Skyt Nielson, & Simonsen, 2014). Significant adverse effects are so rare that they should prompt an investigation for underlying medical causes that may be exacerbated by the medication. The FDA and Health Canada have recommended that stimulants not be used in individuals with known heart disease, including structural heart problems, rhythm abnormalities, and hypertension. Relevant professional organizations in pediatrics, psychiatry, and cardiology are in agreement about the importance of a careful personal and family history for risk factors for sudden death. These include palpitations, syncope or near-syncope, the presence of congenital structural abnormalities, hypertrophic cardiomyopathy, Marfan syndrome, long QT syndrome, and Wolff-Parkinson-White syndrome. During treatment, there should be

regular monitoring of interim cardiovascular history, including concomitantly used medications with cardiovascular effects and pulse and blood pressure checks (Vetter et al., 2008; Warren et al., 2009). In the absence of risk factors or symptoms, the value of additional screening and cardiac assessment or monitoring is unclear and controversial at this time.

Potential for Substance Abuse and Diversion

Stimulants are classified as controlled substances by the Drug Enforcement Agency (DEA). There is increased monitoring of controlled substances due to recent increases in abuse and diversion of both stimulants and opioids. Most states have implemented prescription monitoring programs to limit diversion of medications while supporting access for appropriate medical use (www.deadiversion.usdoj.gov/faq/rx_monitor.htm).

When injected or taken intranasally, stimulants can produce a "high." However, when taken as directed, oral stimulants for ADHD do not induce euphoria or dependence due to their relatively slow uptake into the brain (Volkow & Swanson, 2003). The use of slow-release forms, in which the medication is mixed with other substances and released slowly, makes abuse even less likely to occur (Faraone & Upadhyaya, 2007). Lisdexamfetamine is also less likely to be abused as it is a prodrug, which requires processing in the GI tract, and is unable to be inhaled or used intravenously.

While prescribed stimulants are relatively ineffective for producing euphoria, diversion of stimulants for staying awake for prolonged periods of study or other activities is much more common in both college and high school students (Clemow & Walker, 2014). Approximately 17% of college students report using stimulants that are not prescribed to them for ADHD in this manner (Benson, Flory, Humphreys, & Lee, 2015). Coaching adolescents about managing their medication before they go to college and providing anticipatory guidance about how they will manage requests from peers to share their medication are important aspects of clinical practice for prescribing physicians. Use of medication contracts to encourage appropriate use of stimulants and deter diversion is another option for prevention (Colaneri, Keim, & Adelman, 2017).

In adolescents, a clinical diagnosis of ADHD is correlated with higher rate of substance abuse and substance use disorders (Charach, Yeung, Climans, & Lillie, 2011; Lee, Humphreys, Flory, Liu, & Glass, 2011), particularly with comorbid conduct disorder (Harty, Ivanov, Newcorn, & Halperin, 2011). However, treatment with stimulant medication does not increase this risk (Molina et al., 2013), and it may lower the long-term risk of substance use (Quinn et al., 2017).

Given the high rate of comorbidity of ADHD and substance abuse, physicians need to consider how to best treat such individuals. Current recommendations include psychosocial treatments for both ADHD and substance abuse, careful monitoring, and pharmacological treatment of ADHD with a nonstimulant. However, when nonstimulants are ineffective, the use of a long-acting stimulant, which is less likely to be abused, can be considered (Harstadt, Levy, & Committee on Substance Abuse, 2014).

Initiating and Monitoring Therapy Medication should be only one part of a comprehensive treatment plan that may include behavior therapy and parent training (AAP, 2011). Considerations regarding medication include duration of coverage needed, specific targets for improvement, and any previous treatment experience. In most circumstances, a stimulant is used as a first-line agent (AAP, 2011). School day (8–9 hours) or 12-hour coverage options exist in both stimulant categories. Immediate-release products lasting 3–5 hours may be helpful in several circumstances. They can be used when 12-hour coverage isn't required (for example, on weekends). They may be given after school on certain days to extend the duration of effect (especially to help with after school activities such as homework or sports). They are also sometimes used in the morning to take advantage of their rapid onset when the long-acting formulation being used reaches an effective level too slowly to be effective for the beginning of the school day.

Optimal dose is determined by the effectiveness and side effects profile and is best determined by a dose titration protocol so that a variety of dosage levels can be evaluated. During a dose titration protocol, it is important for parents, students, and teachers to have sufficient opportunity to observe for effects and side effects and to provide feedback. This may be difficult in preschoolers if they do not have a teacher or other outside care provider or with adolescents as they may have multiple teachers during the day (AAP, 2011). Typically, a new medication or dose will be started on the weekend so that parents can monitor their child before sending him or her to school, and then each dose will be monitored for a week. Standardized rating scales should be obtained before starting and at the end of the week on each dose. Most standardized rating scales focus on the core symptoms of ADHD or *DSM-5* criteria. It is also helpful to obtain feedback about functional changes in the areas of completion of activities of daily living, quality of social interaction, and academic accuracy and productivity. When parent and teacher rating scale results do not agree, it is important to consider

reasons for this. It may signal additional diagnoses or symptoms and the need for additional interventions such as parent training or specialized instruction. If a child does not respond or has significant side effects on one stimulant, it is reasonable to try a stimulant from the other class (methylphenidate versus amphetamine; AACAP, 2007). Sometimes a child will show a better response to one formulation or release pattern over another, even within the same stimulant category, and some children who do not tolerate or respond to either stimulant category may respond to a nonstimulant such as atomoxetine or guanfacine (see discussion below). Certain side effects, such as prominent tics, significant anxiety, and persistent irritability, may lead to consideration of a nonstimulant trial or medication combination. Lack of response to a series of rationally considered trials should prompt a reevaluation of the diagnosis, evaluation for coexisting conditions, and an assessment of compliance and other medical or psychosocial factors that may interfere with effective treatment.

School achievement, behavior, relationships, mood, vital signs, and growth velocity should be monitored at baseline, after medication or dose adjustments, and at regular intervals (typically every 3–6 months) to ensure continued beneficial responses and the absence of significant adverse effects. No specific laboratory tests are indicated as part of the monitoring. Clinical history and exam may lead a clinician to order tests to rule out abnormalities that may coexist, exacerbate symptoms, limit effectiveness of medication treatment, or relate to observed side effects. These include ferritin (an iron-binding protein to rule-out iron deficiency anemia) and thyroid hormone levels, a celiac panel, sleep study, electroencephalography (EEG), and bone age x-ray. During childhood it is important to periodically assess whether medication is still effective. Since most children will continue to benefit throughout their school years, it is important to consider with parents and teachers how to best do such an assessment without substantially compromising the student's functioning.

As children become adolescents and young adults, additional targets for medication management become important that make a longer duration of coverage relevant. These include more hours spent doing homework and extracurricular activities, after-school jobs, the requirement for social decision making with increasingly serious implications, and the need for consistent concentration while driving. Driving performance (but not knowledge) has been shown to be impaired in individuals with ADHD, and effective medication treatment has been shown to improve performance (Gobbo & Louzã, 2014).

Stimulants in Preschoolers Stimulants have been used increasingly in children 3–5 years of age, although rates of medication use have stabilized since guidelines for treatment of ADHD in preschoolers were released by the AAP in 2011 (Fiks et al., 2016). Current guidelines recommend behavioral therapy as the first-line treatment for preschool ADHD, although only a small percentage of families enrolled in one large multi-site study of ADHD treatment in more severely affected preschoolers felt that it was sufficient (Greenhill et al., 2006). Dextroamphetamine is the only FDA-approved stimulant for children in this age range. Although methylphenidate has been studied more frequently than dextroamphetamine or mixed salts of amphetamine in preschool children with ADHD, methylphenidate is not FDA approved for children under 6 years of age. The range of effective doses in mg/kg is similar to that found in school-age children, but the percentage of preschool children with a beneficial response may be slightly lower than in elementary school-age children, and side effects, particularly adverse emotional reactivity and growth rate reductions, may be more common (Kratochvil, Greenhill, March, Burke, & Vaughn, 2004; Swanson et al., 2006; Wigal et al., 2006). In a study by Vitiello and colleagues (2007), effectiveness was maintained over 10 months of follow up, but an almost 50% dose increase was required.

Typically, immediate-release methylphenidate up to three times daily has been the treatment regimen used in most studies; there is little information about the use of long-acting formulations in preschoolers. Preliminary open-label studies suggest effectiveness for a longer-acting beaded methylphenidate formulation (Maayan et al., 2009), but further research has been limited. There are few studies on the use of nonstimulants in this age range.

Nonstimulant Medications for ADHD Between 10%–30% of children with ADHD will not benefit from stimulants or will have adverse side effects that preclude their use. Nonstimulant medications may be helpful in this group. These medications fall into three categories: norepinephrine reuptake inhibitors, antidepressants, and alpha-2-adrenergic agonists.

Norepinephrine Reuptake Inhibitors Atomoxetine (e.g., Strattera) is the only norepinephrine reuptake inhibitor that is FDA approved for the treatment of ADHD (in individuals 6 years of age and over). It is effective in reducing ADHD symptoms compared with placebo and is not inferior to stimulant medications (Gayleard & Mychailyszyn, 2017; Shang, Pan, Lin, Huang, & Gau, 2015). A comprehensive review

of atomoxetine trials in children, teens, and adults has demonstrated that atomoxetine improves parent and teacher ratings of attention and decreases their ratings of hyperactivity and impulsivity at doses of 1.2–1.4 mg/kg/day (Bushe & Savill, 2014; Savill et al., 2015; Schwartz & Correll, 2014). There is no clear benefit to increased-dose or twice-daily dosing in children with ADHD only (Waxmonsky, Waschbusch, Akinnusi, & Pelham, 2011), but benefits persist in the absence of serious adverse effects for 2–4 years (the longest duration thus far reported) without development of tolerance or progressive ineffectiveness over time (Donnelly et al., 2009; Garnock-Jones & Keating, 2009; Kratochvil et al., 2006). It is effective for ADHD in children and adolescents with a variety of coexisting conditions and does not worsen (or may improve) coexisting symptoms, including tics and anxiety (Garnock-Jones & Keating, 2009) and oppositional defiant disorder (Dittman et al., 2011). Nonetheless, it does not appear to be more effective in children with internalizing disorders than those without internalizing disorders (Scott, Ripperger-Suhler, Rajab, & Kjar, 2010). Preliminary evidence suggests that the benefits of atomoxetine may exceed effects on core ADHD symptoms to include improvements in reading and executive function skills (Adler, Clemow, Williams, & Durell, 2014; Maziade et al., 2009; Wehmeier et al., 2012). There are some studies that have suggested improvement in endorsement of core ADHD symptoms in preschool-age children (Ghuman et al., 2009a), but functional and clinical improvement were less apparent (Kratochvil et al., 2011).

Atomoxetine may take a few days before one begins to see effects and several weeks to reach the maximum effect. Similarly, beneficial effects may dissipate gradually when it is discontinued, and some children remain improved over baseline (Buitelaar et al., 2007); there is no adverse effect of abrupt discontinuation (Wernicke et al., 2004). It is generally given once daily in the morning but can be given twice daily to extend coverage into the evening. Fatigue and gastrointestinal upset are relatively common side effects, but atomoxetine is unlikely to cause sleep disturbance.

Gastrointestinal upset is typically prevented by giving the medication with food; foods containing protein or fat are particularly effective for this purpose. Some children experience weight loss during the first few months of treatment, but the average reduction in height and weight percentiles is generally maximal after 18 months of continued use. The loss is about 2% at 2 years and is resolved by 5 years in all except the largest children (Spencer et al., 2007). Growth effects can occur with atomoxetine but do not appear to be clinically significant over longer time periods. In a 5-year prospective

study, maximal growth decrements occurred in the second year of treatment. Weight was 9.9 percentile points below that expected at 15 months of treatment, and height was 6.6 percentile points below expectations at 18 months. At 5 years, average height and weight percentiles were similar to the starting values for the majority of children. Some children who were above the mean for weight or height initially remained at lower percentiles at 5 years (Spencer et al., 2007).

Other side effects include dizziness, irritability, somnolence, and allergic reactions. Increases in pulse and blood pressure do occur, but these are typically not clinically significant. Other, more significant cardiovascular events have not been reported. Prescribing information includes a black box warning about the increased risk of suicidal ideation; thus, monitoring for depression, mood instability, and behavioral activation is critical.

Atomoxetine is metabolized by cytochrome P450 (CYP2D6), a system of liver enzymes important in the metabolism of many drugs, and levels may be affected in individuals who are rapid or slow metabolizers and by other medications that inhibit CYP2D6. Although genotyping for these variants is not currently a routine practice, dose reduction should be considered in those with prominent early side effects (ter Laak et al., 2010) or those taking another medication that is a CYP2D6 inhibitor, such as a selective serotonin reuptake inhibitor (SSRI; Sauer, Ring, & Witcher, 2005). A recent review of safety reported that incidents of hepatotoxicity are rare in children and adolescents treated with atomoxetine (Reed et al., 2016).

Antidepressants Several types of antidepressants have been found to be effective in children with ADHD, although they are not FDA approved for this purpose. A recent *Cochrane Review* of tricyclic antidepressants (TCAs) in children (including desipramine and nortriptyline) reported that the TCAs improve ADHD symptoms in children compared with a placebo, although they were not as effective as stimulants for most children (Otasowie, Castells, Ehimare, & Smith, 2014). Using a TCA may also be indicated when there are significant side effects from other medications or when there is an increased risk for substance abuse/diversion.

Compared with stimulants, TCAs have advantages that are like those of atomoxetine. They have a longer duration of action, low abuse potential, and tend not to exacerbate tics. However, they have many more potentially problematic cardiovascular, neurologic (tingling, incoordination, tremors) and anticholinergic (blurred vision, dry mouth) side effects that limit their use. Drug levels should be checked, as there can

be large individual differences in metabolism of these medications (Banaschewski et al., 2004). Electrocardiograms must be obtained at baseline and monitored for cardiovascular changes. Overdoses can be lethal, and a few cases of sudden death, presumably from cardiac arrhythmias, have occurred in children taking appropriate doses of desipramine, although causality could not be clearly established (Popper, 2000).

Bupropion is a chemically distinct antidepressant whose precise mechanism of action in ADHD treatment remains unknown. It is a weak dopamine and norepinephrine reuptake inhibitor; this may explain its benefit. It has been shown to improve ADHD symptoms in both children and adults. Beneficial effects may be detected as early as 3 days after initiation of treatment, but maximum effects may not be seen until 4 weeks of treatment (Conners et al., 1996). On average, the magnitude of the effects is similar to or slightly less than those of stimulants (Jafarinia et al., 2012; Maneeton, Maneeton, Srisurapanont, & Wootliluk, 2011), but side effects are more commonly reported with methylphenidate (Mohammedi, Hafezi, Galeiha, Hajiaghaee, & Akhondzadeh, 2013). Gastrointestinal complaints, drowsiness, and rashes are the most common side effects with bupropion; insomnia can also occur. Bupropion treatment is associated with a slightly increased risk of drug-induced seizures (about 4 per 1,000 individuals). The use of high doses, a previous history of seizures, and the presence of an eating disorder seem to increase the risk for seizures. Bupropion also may exacerbate tic disorders. Both sustained- and extended-release formulations have been shown to provide extended symptom control throughout the day in adults (Maneeton, Maneeton, Srisurapanont, & Martin, 2014; Wilens et al., 2005).

Alpha-2-Adrenergic Agonists The alpha-2-adrenergic agents clonidine and guanfacine have been used for the treatment of ADHD since the 1980s. Clonidine has also been used for aggression and insomnia (Banaschewski et al., 2004). Short-acting guanfacine and clonidine are not FDA approved as treatment for ADHD but have been used off-label. However, in 2009, the FDA approved a long-acting form of guanfacine (Intuniv) for the treatment of ADHD in children and adolescents. Recent Phase 3 trials have shown extended-release guanfacine to be effective in reducing ADHD symptoms (Hervas et al., 2014; Wilens et al., 2015). This is true both as monotherapy and as adjunctive therapy with stimulants. There is no difference between morning and evening administration of extended-release guanfacine (Newcorn et al., 2013). As with other medications that affect primarily the noradrenergic system, clonidine

and guanfacine do not tend to exacerbate tics and may reduce them (Bloch, Panza, Landeros-Weisenberger, & Leckman, 2009). Disadvantages of the immediate-release forms of these medications include 1) sedation and dry mouth, 2) rapid peaking of levels, and 3) decreased compliance as a result of the need for frequent dosing (reviewed in Sallee, 2010). The most common side effects are somnolence, headache, and fatigue, but they tend to subside over time (Faraone & Glatt, 2010; Hervás et al., 2014; Wilens et al., 2015). Cardiovascular changes have been noted to be mild and not clinically significant. Open-label continuation of treatment has demonstrated safety and effectiveness for up to 2 years (Biederman et al., 2008; Sallee et al., 2009). Although there is a theoretical concern about rebound hypertension with abrupt discontinuation, this was not found in a study of abrupt discontinuation in healthy young adults (Kisicki, Fiske, & Lyne, 2007). A clonidine patch changed weekly has been available since 1984, although it is not FDA approved for the treatment of ADHD. In 2010, a twice-daily, extended-release clonidine tablet (Kapvay; Shionogi, Inc.) was approved for use in children and adolescents ages 6 to 17. Clinical trials support the safety and efficacy of extended-release clonidine for the treatment of ADHD symptoms as both monotherapy (Jain, Segal, Kollins, & Khayrallah, 2011) and adjunctive therapy with stimulants (Kollins et al., 2011).

TREATMENT WITH COEXISTING CONDITIONS

Treatment of Children with ADHD and Intellectual Disability

ADHD can be diagnosed in the presence of intellectual disability when inattention or hyperactivity and impulsivity exceed expectations for the child's delayed developmental level and cause additional functional impairment. Studies suggest that methylphenidate can be effective for ADHD symptoms and cognitive task performance in preschoolers and school-age children with intellectual disability; however, they have a lower response rate (around 50%) and an increased risk for side effects, such as stereotypic behavior and emotional lability (Deutsch, Dube, & McIlvane, 2008; Ghuman et al., 2009b; Handen & Gilchrist, 2006). The likelihood of a positive response does not appear to be related to IQ or autistic features (Simonoff et al., 2013). Young children with an intellectual disability are more likely to be prescribed a nonstimulant (Osunsanmi & Turk, 2016). Atomoxetine does have positive effects on ADHD symptoms based on a recent review (Aman et al., 2014), but lower IQ may decrease efficacy of treatment

(Mazzone, Reale, Mannino, Cocuzza, & Vitiello, 2011). An initial double-blind, placebo-controlled study of guanfacine in a small number of children with intellectual disability, autism, or both who previously failed methylphenidate treatment showed improvements in hyperactivity and aberrant behavior but not in attention (Handen, Sahl, & Hardan, 2008). Atypical antipsychotics, particularly risperidone (Risperdal), may also be helpful for hyperactivity and disruptive behaviors in children with intellectual disability (Filho et al., 2005; Handen & Gilchrist, 2006; Olfson, Crystal, Huang, & Gerhard, 2010); however, there are few studies using double-blind, placebo-controlled methods (Thompson, Maltezos, Paliokosta, & Xenitidis, 2009). An open-label study in children and adolescents showed continued effectiveness for up to 2 years (Reyes, Croonenberghs, Augustyns, & Eerdeken, 2006). The development of metabolic syndrome (the combination of obesity, hypertension, high cholesterol, and high blood sugar levels) is a significant risk with the use of atypical antipsychotics (Weiss et al., 2009; see Chapter 38).

Treatment of ADHD and Autism Spectrum Disorder

Older studies of children with autism suggested that the benefit to side effects ratio of stimulants (primarily methylphenidate) was not sufficient to warrant their use in this population; however, newer studies show positive effects (Abanilla, Hannahs, Wechsler, & Silva, 2005). Since a higher IQ is associated with better response, more recent inclusion of individuals with milder autism spectrum symptoms and higher IQ may have shifted the results.

In one study, extended-release methylphenidate was shown to improve hyperactivity, impulsivity, and inattention in children with ASD compared with a placebo, with both parents and teachers noting positive effects that were highly concordant (Pearson et al., 2013). Positive effects have also been reported on attention to social interaction and self-regulation (Jahromi et al., 2009). However, methylphenidate does not appear to help rigidity or stereotypic behavior, and an increased susceptibility to side effects has been noted compared with the rates seen in children with ADHD in the absence of ASD or intellectual disability (Handen, Johnson, & Lubetsky, 2000).

A randomized, controlled trial (RCT) showed modest improvements in ADHD symptoms with atomoxetine in 6–17 year olds with ASD, with no serious adverse effects (Harfterkamp et al., 2012). Extended-release guanfacine was found to be effective for treating ADHD symptoms in children with ASD, with minor

side effects on pulse and blood pressure noted during one RCT (Scahill et al., 2015). Earlier studies showed similar modest effects with clonidine for ADHD target symptoms with ASD (Jaselskis, Cook, Fletcher, & Leventhal, 1992), but more recent studies in this population are limited. If using these medications, clinicians must be vigilant for both positive and negative changes in behavior, as well as physical side effects.

Atypical antipsychotics such as risperidone and aripiprazole have been shown to improve irritability, aggression, and stereotyped behavior in children with autism (Arnold et al., 2010; Marcus et al., 2011; McDougle et al., 2005). Risperidone may improve hyperactivity (Posey, Stigler, Erickson, & McDougle, 2008) and impulsivity as well (Lemmon, Gregas, & Jeste, 2011). Positive behavioral effects were noted in long-term studies as well (Kent, Hough, Singh, Karcher, & Pandina, 2013). There is less evidence for effectiveness of antidepressants, anxiolytics, and mood stabilizers (Aman, Farmer, Hollway, & Arnold, 2008).

Treatment of ADHD and Externalizing Disorders (Oppositional Defiant Disorder and Conduct Disorder)

Individuals with ADHD and conduct disorder are at much higher risk of developing substance abuse or antisocial personality disorder and of being involved in criminal activity than individuals with ADHD alone (Turgay, 2009). Oppositional defiant disorder and conduct disorder are difficult to treat (see Chapter 27), but they typically respond best to comprehensive approaches involving both behavioral interventions and medication (Reale et al., 2017). About 60% of individuals with oppositional defiant disorder will develop conduct disorder (Turgay, 2009).

Pharmacologic studies may evaluate individuals with oppositional defiant disorder and conduct disorder separately or as one experimental group. Furthermore, some studies identify the characteristic of aggression rather than a specific diagnosis as the independent variable. The term *externalizing disorders* will be used hereafter to refer to all of these conditions collectively.

Individuals with ADHD and externalizing disorders respond well to stimulants for their ADHD symptoms. In addition, the externalizing symptoms are likely to improve, so stimulants should be considered the first-line pharmacologic treatment for externalizing disorders with ADHD (Pringsheim, Hirsch, Gardner, et al., 2015). When children with aggression appear to be stimulant nonresponders, a systematic, carefully monitored titration protocol to identify the optimal dose—in

combination with behavior therapy—may show sufficient improvement up to 50% of the time to support continued stimulant monotherapy (Blader, Pliszka, Jensen, Schooler, & Kafantaris, 2010). Atomoxetine has been shown to be equally efficacious for ADHD symptoms with or without additional externalizing disorders (Dell’Agnello et al., 2009), and recent comparison studies show that it is as effective as stimulants for the treatment of comorbid externalizing symptoms (Garg, Arun, & Chavan, 2015). Both stimulants and atomoxetine have a small but finite risk of exacerbating depression, mood lability, or aggression, so these symptoms should be monitored with regular follow-up visits. Extended-release guanfacine has also been shown to be effective for treating ADHD and reducing externalizing symptoms (Connor, Steeber, & McBurnett, 2010; Wilens et al., 2015), with less evidence demonstrated for clonidine monotherapy (Connor et al., 2010; Ming, Mulvey, Mohanty, & Patel, 2011). Additional medications that demonstrate effectiveness for some individuals with externalizing disorders include mood stabilizers (such as lithium or divalproex sodium), SSRIs, and atypical antipsychotics (Loy, Merry, Hetrick, & Stasiak, 2017; Nevels, Dehon, Alexander, & Gontkovsky, 2010; Pliszka et al., 2006). Medication combinations may eventually prove to be most useful for this group of children, but they require further study before they can be FDA approved (McBurnett & Pfiffner, 2009; Spencer, 2009).

Treatment of ADHD and Internalizing Disorders

The treatment of children with ADHD and anxiety can be challenging because the ADHD core symptoms may not respond as well to methylphenidate (Ter-Stepanian, Grizenko, Zappitelli, & Joobar, 2010) or because anxiety may be exacerbated by stimulants. Recent studies have found a reduction in social phobia and separation anxiety in children with comorbid ADHD that are treated with stimulants (Golubchik, Golubchik, Sever, & Weizman, 2014; Golubchik, Sever, & Weizman, 2014). Although anxiety may inhibit impulsivity, it also may make working memory impairments worse (Schatz & Rostain, 2006). Psychosocial intervention such as CBT has been shown to be particularly efficacious in children with coexisting anxiety disorders and may be a critical component of treatment in this group of children (Houghton, Alsalmi, Tan, Taylor, & Durkin, 2017; MTA Cooperative Group, 1999b). One algorithm derived by expert consensus (The Texas Children’s Medication Algorithm) recommends initiating treatment with a stimulant and then adding an SSRI if anxiety does not improve sufficiently when the ADHD symptoms are

treated effectively (Pliszka et al., 2006). Atomoxetine has been shown to be effective in children with ADHD and comorbid anxiety (Hutchison, Ghuman, Ghuman, Karpov, & Schuster, 2016) and may allow some children to be treated with one rather than two medications. When symptoms of depression are present, the more severe disorder should be treated first, with an SSRI being used for depression and a stimulant for ADHD (Pliszka et al., 2006). Other antidepressants that also treat ADHD symptoms (TCAs and bupropion) are options if a stimulant is not tolerated or is not effective. The finding that SSRIs and other antidepressants can increase suicidal ideation in individuals with depression underscores the need for close monitoring even with newer agents (Herrick, McKenzie, Cox, Simmons, & Merry, 2012).

Treatment of ADHD with Tic Disorders

Although the presence of tics or a personal or family history of Tourette syndrome are listed as contraindications to stimulant use by the pharmaceutical companies that manufacture these medications, this stance appears to be unnecessarily restrictive (see Side Effects). ADHD symptoms may cause much more functional impairment than do tics and thus be the priority for treatment (Denckla, 2006; Pringsheim & Steeves, 2011). Most children do not have significant tic exacerbations in response to therapeutic stimulant doses (Cohen et al., 2015). Nonstimulant medications (atomoxetine, guanfacine, and clonidine) can be tried first and may improve existent tics (Bloch et al., 2009). TCAs may also treat ADHD without inducing or exacerbating tics, but their safety profile is a limitation. If stimulants are the only effective medication and do exacerbate tics, the addition of guanfacine or clonidine is recommended (AACAP, 2007). If these are not effective, risperidone or pimozide may be used for tic suppression (Pliszka et al., 2006), along with newer atypical antipsychotics, such as aripiprazole, which have shown improved efficacy with fewer side effects. The antiepileptic medication topiramate may also be an effective tic suppressant, though further study is needed (Yang et al., 2016).

Treatment of ADHD with Medication Combinations

As described previously, it is common for individuals with ADHD to have one or more coexisting conditions. Medications approved for the treatment of ADHD do not typically address the coexisting symptoms, with some exceptions—atomoxetine may have positive effects on anxiety (Kratochvil et al., 2005; Spencer, 2009)

and oppositional defiant disorder (Dittman et al., 2011), and alpha-adrenergic agonists may improve aggression (Connor et al., 2010; Sallee, 2010) and tics (Bloch et al., 2009; Pliszka et al., 2006).

Combinations of methylphenidate with alpha-adrenergic agonists (Kollins et al., 2011; Wilens et al., 2012), SSRIs, (Spencer, 2009), atomoxetine (Kratochvil et al., 2005; Wilens et al., 2008), and atypical antipsychotics have all shown some benefit for individuals with ADHD and coexisting conditions (Sallee, 2010; Spencer, 2009). However, there are limited data on combination pharmacological treatments in children with ADHD (Catalá-López et al., 2017). Preliminary investigation indicates that atomoxetine with fluoxetine is a safe and effective combination for ADHD with coexisting anxiety or depressive symptoms. The safety information is important given that both medications are substrates for P450–CY2D6 liver metabolism (Kratochvil et al., 2005). In addition, there is evidence for a combined efficacy of atomoxetine and stimulants (Ozbaran, Kose, Yuzuguldu, Atar, & Aydin, 2015), but larger studies are needed as adverse effects can be more common (Hammerness et al., 2009b). Despite increasing evidence for effectiveness and the widespread need for optimal management of ADHD with coexisting conditions, there are only two recent FDA-approved medication combinations for ADHD or ADHD with coexisting conditions, sustained-release clonidine (Kapvay; Shionogi, Inc.) and sustained-release guanfacine (Intuniv; Shire, Inc.) with a stimulant.

ALTERNATIVE THERAPIES

Elimination diets, nutrient supplementation, and brain training techniques are the most frequently studied alternative treatments for ADHD. Recently, benefits of aerobic exercise and mindfulness meditation have also been reported. Dietary treatments include three different approaches: the elimination of certain foods or additives, nutrient supplementation, and the provision of a “high-quality,” whole-foods diet that decreases additives and increase nutrients. The two most commonly identified additive-free diets are the Feingold Program (elimination of artificial colors and flavors; the preservatives BHA, BHT, and TBHQ; and naturally occurring salicylates found in some fruits and vegetables), and a British version (elimination of artificial colors and the preservative sodium benzoate). There are, in fact, no accurately designed studies of the Feingold diet. Studies in the early 1970s, which purported to test this hypothesis, contained methodological flaws that would have minimized positive results. Nonetheless, 10%–20% of children were noted to respond, and preschoolers were noted to have a much higher response

rate (Bateman et al., 2004; Kaplan, McNichol, Conte, & Moghadam, 1989). Studies focusing on the role of artificial colors and sodium benzoate in the general population of children in the United Kingdom (not selecting for those identified as having ADHD-related symptoms) have revealed small, but significant detrimental effects of these substances on the behavior of 3-year-old and 8- to 9-year-old children (Bateman et al., 2004; McCann et al., 2007). The adverse effect of additives in a subgroup of children in this study was moderated by polymorphisms in histamine degradation genes, suggesting that histamine response may play a role in the effects of additives on behavior (Stevenson et al., 2010). Meta-analyses of double-blind, placebo-controlled elimination diet trials have found positive effects, though with relatively small effect sizes (Nigg, Lewis, Edinger, & Falk, 2012; Pelsser, Frankena, Toorman, & Pereira, 2017; Schab & Trinh, 2004; Sonuga-Barke et al., 2013), likely due to significant response in a relatively small subgroup of subjects. In the future, it will be important to elucidate the factors that predict response as well as underlying mechanisms (Nigg & Holton, 2014).

The elimination of specific foods may also improve ADHD-related symptoms. Commonly allergenic foods are typically most often implicated, and in past studies the children who reacted to these foods also reacted to artificial colors (Carter et al., 1993; Egger, Carter, Graham, Gumley, & Soothill, 1985; Schmidt et al., 1997). A recent controlled, though not blinded, study of this approach in young children with ADHD resulted in an approximately 50% improvement on parent and teacher ADHD rating scales (Pelsser et al., 2009). The mechanism for this observation is unknown, but case reports documented improvement in ADHD symptoms when IgG-mediated food reactions were eliminated (Ritz & Lord, 2005). However, there are no well-controlled studies at this time. The elimination of sugar has not been found to be an effective intervention (Wolraich, Wilson, & White, 1995). It is important to note that elimination of high salicylate fruits and vegetables (in the Feingold Program) or allergenic foods (in an oligoantigenic diet) are not meant to be long-term practices, but rather following a 2- to 6-week full elimination, individual foods are added back singly to identify specific triggers. Most children do not need to eliminate all of the potential triggers. These diets can be nutritionally adequate for children who eat a variety of foods, but children who eliminate multiple foods for extended periods might benefit from consultation with a knowledgeable dietitian to ensure that appropriate substitutes are chosen to ensure adequate long-term nutrient intake.

Children with ADHD have been shown to be relatively deficient in iron, zinc, magnesium, and vitamin D

(Bener, Kamal, Bener, & Bhugra, 2014; Sharif, Madani, Tabatabaei, & Tabatabaee, 2015; Wang, Huang, Zhang, Qu, & Mu, 2017), but treatment studies have shown limited effects (Hariri & Azadbakht, 2015; Lange et al., 2017). Studies of multinutrient supplementation, however, have shown positive effects under randomized, blinded, placebo-controlled conditions in both adults (Rucklidge, Frampton, Gorman, & Boggis, 2014) and children (Rucklidge, Eggleston, Johnstone, Darling, & Frampton, 2017) with ADHD. In children, attention, emotional regulation, aggression, and overall function improved, but hyperactive-impulsive symptoms did not. "Megadoses" of vitamins or minerals can have toxic effects and are not recommended.

Levels of polyunsaturated fatty acids (PUFAs), including the omega 3s, docohexanoic acid (DHA) and ecosapentanoic acid (EPA) and the omega 6s, arachidonic acid (AA), and gamma-linoleic acid (GLA), are lower in children with ADHD than controls (Montgomery, Burton, Sewell, Spreckelsen, & Richardson, 2013). Omega-3s are important components of neuronal cell membranes, and omega-6s are important in cell-to-cell signaling in the brain and periphery. Supplementation has shown positive effects, with small effect sizes, when a combination of the three anti-inflammatory PUFAs (EPA, DHA, and GLA) have been used in adequate doses for a sufficient length of time (reviewed in Cooper, Tye, Kuntsi, Vassos, & Asherson, 2016; Derbyshire, 2017; Gillies, Sinn, Lad, Leach, & Ross, 2013; Hawkey & Nigg, 2014). While adding PUFAs to effective methylphenidate treatment does not appear to provide additional benefit, one study indicates that children who do not have a good response to methylphenidate may respond to PUFAs (Perera, Jeewandara, Seneviratne, & Guruge, 2012). Recently, the FDA approved a combined omega-3-phosphatidylserine product as a medical food (Vayarin; Vaya Pharmaceuticals), which has been found to be effectively incorporated into brain cell membranes (Vaisman et al., 2008). It has shown positive effects in children with ADHD, but only in a subgroup; thus, overall effect sizes are small. This and other studies suggest that oppositional and emotional dysregulation symptoms may respond more so than core ADHD symptoms (Cooper et al., 2016; Manor et al., 2012). Since children with ADHD appear to be deficient due to altered metabolism of PUFAs rather than decreased intake (Colter, Cutler, & Meckling, 2008), initial measurement of PUFA levels, followed by individualized treatment, may be a more appropriate way to assess the effects of supplementation. For example, a recent study in which EPA treatment alone did show positive effects also found higher levels of arachidonic acid (an omega-6 EFA) among responders (Gustafsson et al., 2010).

There is an association between unhealthy diets and more symptoms related to ADHD (and other childhood disorders) when children are exposed prenatally and during early childhood (Jacka et al., 2013) and a two-fold risk for diagnosis of ADHD in adolescence when children follow a diet that is higher in fat, saturated fat, and sugar than recommended (Howard et al., 2011). Similarly, the risk for ADHD correlates inversely with adherence to the Mediterranean diet (low in processed foods and sugars and high in fruits, vegetables, fish and olive oil; Ríos-Hernández, Alda, Farran-Codina, Ferreira-García, & Izquierdo-Pulido, 2017). While these studies demonstrate an association between these differing diets and risk for ADHD, it is possible that dietary differences may be a consequence of, rather than cause of, ADHD symptoms. Further research is needed to establish a causative role of these diets in the genesis of ADHD symptoms. Overall, science is moving in the direction that supports a “clean,” whole-foods based diet with adequate nutrients and healthy fats for ADHD as well as for other mental health conditions.

Several techniques that “train” brain activity with the goal of improving attention and working memory are under investigation. EEG biofeedback is the treatment that has been studied most extensively. Quantitative EEG studies indicate that subjects with ADHD have a lower level of alpha and beta brain waves, which are associated with alert, thinking states, and a higher level of theta and delta waves, which are associated with drowsiness. EEG biofeedback uses computer technology to train the individual to produce more of the brain wave patterns associated with concentration and to suppress those associated with overarousal or underarousal (Monastra, 2008). There is some evidence for effectiveness in improving ADHD symptoms and computerized measures of attentional control, but this tends to be stronger when control subjects have no treatment (rather than sham treatment) and are therefore not blinded (Holtmann, Sonuga-Barke, Cortese, & Brandeis, 2014). Persistence of treatment effects at 6 months is inconsistent (Geladé et al., 2017; Gevensleben et al., 2010) as is generalization of improved EEG measures to improved task performance (Janssen et al., 2016). Some recent randomized controlled trials found positive effects in combination with medication (González-Castro, Cueli, Rodríguez, García, & Álvarez, 2016; Lee & Jung, 2017), which require further investigation. It has been proposed that differences in specific training, duration of treatment, and outcome measures may contribute to inconsistent results. It has also been proposed that combining future neurofeedback studies with functional MRI may help to clarify the impact of neurofeedback training on brain

activity in specific regions during task performance, which may provide insight into variable results (Sitarum et al., 2017).

Computerized working memory training is the next most frequently studied brain training approach. Studies of this approach also show somewhat inconsistent results, with some showing significant positive effects on a range of outcomes including memory, executive skills, and behavior (Farias et al., 2017), while others show modest effects (Kirk, Gray, Ellis, Taffe, & Cornish, 2017) or no significant effects at all (Hitchcock & Westwell, 2017). Reviews indicate that improvements are stronger for the specific trained skill (working memory) than for more applied skills (academic achievement and ADHD symptom control), and effects are smaller when treatment and control groups are blinded to the intervention (Rapport, Orban, Kofler, & Friedman, 2013; Robinson, Kaizar, Catroppa, Godfrey, & Yeates, 2014; Sonuga-Barke, Brandeis, Holtmann, & Cortese, 2014). Studies show task-dependent enhancement of brain activation in expected regions after training, and, as with neurofeedback, these neurophysiologic measures may be used in future studies to help clarify inconsistencies in outcome among current studies (Hoekzema et al., 2010; Stevens, Gaynor, Bessette, & Pearlson, 2016). While brain training approaches may be beneficial for some students, the current consistency and quality of evidence does not allow for a uniform recommendation for these treatments, which can be time-intensive and costly.

Aerobic exercise appears to provide benefits, not only for core symptoms of ADHD, but also for social, emotional, and behavioral outcomes as well as some cognitive/executive function and motor skills. The quality and consistency of studies does not allow the development of a specific exercise prescription at this time, however, and it should be considered an adjunctive intervention (Cerrillo-Urbina et al., 2015; Hoza, Martin, Pirog, & Shoulberg, 2016; Kamp, Sprlich, & Holmberg, 2014; Tan, Pooley, & Speelman, 2016). Mindfulness meditation can strengthen attentional control, and there is preliminary evidence for benefits for individuals with ADHD (Cassone, 2015).

OUTCOME

Symptoms of ADHD decline over time, and rates of persistence vary widely depending on methodology, with about 30%–50% showing persistence of the disorder and over 60% showing persistence of some symptoms (Caye et al., 2016). Unfortunately, even with a reduction in core symptoms, longitudinal follow-up studies indicate that functional impairments persist (Lee, Sibley, & Epstein, 2016).

Compared with their peers, young adults with ADHD have lower educational and employment performance and attainment; fewer friendships and more social problems; poorer driving records; and a higher chance of sexually transmitted disease, unplanned pregnancy, injuries, and even mortality (Dalsgaard, Ostergaard, Leckman, Mortensen, & Pedersen, 2015; Fischer, Barkley, Smallish, & Fletcher, 2007; Loe & Feldman, 2007; Wehmeier, Schacht, & Barkley, 2010). Youth with ADHD are also at higher risk for emerging coexisting conditions in their young adult years, including antisocial behavior, substance abuse, mood, anxiety, and eating disorders (Groenman, Janssen, & Oosterlaan, 2017; Klein et al., 2012; Nazar et al., 2016; Yilmaz et al., 2017). Inattention predicts poor academic outcome, but hyperactivity tends to predict the antisocial behavior and other adverse outcomes (Sasser, Kalvin, & Bierman, 2016). The presence of conduct disorder predicts some of the most severe outcome risks, including failure to graduate from high school, early sexual activity and parenthood, antisocial behavior, and substance use (Barkley et al., 2006; Caye et al., 2016).

Understanding the factors that result in the sub-optimal outcomes faced by youth with ADHD is hampered by the difficulty in performing well-controlled, prospective, long-term studies. The heterogeneity in ADHD symptoms and trajectories also hamper outcome studies. For example, studies show that there are subsets of children with low levels of symptoms that remain stable, symptoms that decline or even resolve over time, and high levels of symptoms that remain high (Sasser et al., 2016). Childhood predictors of persistent symptoms into adulthood include the severity of symptoms in childhood (Caye et al., 2016) as well as several factors that predict poorer outcomes for all children, including lower IQ, the presence of other mental health conditions, limited family resources, marital problems, and decreased parental monitoring/involvement (Roy et al., 2017). Biological factors associated with persistence and severity of ADHD in population studies include the **polygenic risk score** and pattern of cortical development. A large number of gene variants confer risk for ADHD, and having a larger number of these (i.e., a higher polygenic risk score) is correlated with baseline symptom severity, symptom persistence, and more comorbid diagnoses (Riglin et al., 2016). Different sets of genes are related to baseline severity and persistence (Pingault et al., 2015). Longitudinal imaging studies suggest that atypical cortical development is evident in those individuals with persistent or worsening trajectories, while a pattern of cortical development that is more similar to controls was seen in those with declining/remitting symptoms (Shaw et al., 2013).

When children receive evidence-based treatment, including medication and psychosocial interventions, there are also different response trajectories. The MTA study has been the largest clinical trial of ADHD treatments to date (MTA Cooperative Group, 1999a). It was a prospective multisite treatment study of 576 children with ADHD combined presentation (ADHD-C) between the ages of 7 and 9 years. Children were randomized into one of four treatment groups: medication management, intensive behavioral treatment, medication and intensive behavioral treatment, and standard community care. After 14 months of treatment, they returned to community treatment; the participants were then followed prospectively for 16 years (Hechtman et al., 2016).

In this study, there were three patterns of initial response to treatment: 1) About 34% of the subjects showed an initial mild improvement that gradually increased over time, 2) about 52% showed an initial substantial improvement that was maintained over time, and 3) about 14% had an initial substantial improvement and then deteriorated over time. Long-term outcomes paralleled initial treatment responses regardless of the specific treatment (Hechtman et al., 2016). The second group had the most favorable outcome. They were less impaired at baseline, had less psychosocial adversity, and were more frequently in the medication or combined treatment groups. The third group had the poorest outcome. They had increased severity at baseline, lower IQs, decreased social skills, more coexisting conditions, and more psychosocial risk factors.

Across studies, subgroups with a trajectory of resolving or declining symptoms have a lower level of negative outcomes than those with persistent symptoms. Those with resolving symptoms may not differ from controls in terms of mood and anxiety disorders and substance use (Hechtman et al., 2016), but they still have poorer educational and employment outcomes (Barkley, 2016).

Unfortunately, treatment with the evidence-based interventions of medication and behavior therapy, while showing robust short-term benefit, does not consistently translate into improved long-term outcomes. The initial benefit of medication treatment in the MTA study did not appear to hold up over time, even in those who remained on medication (Swanson et al., 2017). It must be noted, however, that there is a very limited number of studies of long-term medication or psychosocial treatments. It must also be acknowledged that, in the MTA study, those who remained on medication or continued to receive psychosocial treatment in the community most likely had the severest symptoms. There is, however, evidence for a positive impact of medication treatment on academic

achievement when children, adolescents, and young adults are actively taking medication (Lu et al., 2017; Scheffler et al., 2009). There is also a positive impact on driving safety (Chang et al., 2017), injuries (Man et al., 2017), and hospital contacts (Dalsgaard, Nielson, & Simonsen, 2014), as well as a likely reduction in substance abuse (Quinn et al., 2017) and criminality (Dalsgaard et al., 2014).

Improvements in social, educational, employment, and mental health outcomes are not as well documented, and they are also harder to measure. Some studies do show positive outcomes that last beyond short-term treatment. The MTA study showed positive effects of combined psychosocial and medication treatment in children with coexisting disorders, especially anxiety disorders, and improved outcomes with treatment for children with the most psychosocial disadvantage (Swanson et al., 2008). There also appears to be a benefit from pharmacologic, nonpharmacologic, and combined treatment on measures of self-esteem and some measures of social function (Harpin, Mazzone, Raynaud, Kahle, & Hodgkins, 2016).

It has been theorized that current evidence-based treatments may not sufficiently sustain, generalize, or affect key areas of functional impairment because they do not fully target the neurocognitive and functional skills deficits associated with ADHD (Chacko, Kofler, & Jarrett, 2014). There is some evidence for improved functional outcomes with skill-based training for children and adolescents. This includes organizational and study skills in combination with parent training in the provision of reinforcements for using learned skills (Abikoff et al., 2013; DuPaul et al., 2014; Evans et al., 2014) as well as for cognitive behavior therapy in young adults (Weiss et al., 2012). These approaches are only beginning to be widely used, and, unfortunately, sustained treatment is not widely accessible. It remains to be determined whether the combination of skill-based, sustained, and intensive psycho-social-educational treatments with medication and biological optimization (nutrition and sleep and stress management) can improve long-term outcomes for children with ADHD.

SUMMARY

- ADHD is a prevalent neurodevelopmental condition that has a significant impact on the lives of affected children, their families, and the educational and medical/mental health systems.
- The core features of ADHD (difficulty sustaining mental effort, hyperactivity, and impulsivity) lead to impairment in academic, occupational, social, and adaptive functions without effective intervention.

- Coping with ADHD is made more complicated by commonly coexisting conditions, including learning disorders, oppositional defiant disorder, and anxiety disorders.
- ADHD is highly genetic, but adverse conditions in the prenatal and perinatal period can contribute to symptoms. Multiple lines of evidence suggest a biological basis involving frontal cortical, basal ganglia, and cerebellar pathways and biogenic amine neurotransmitters, particularly dopamine and norepinephrine.
- Treatments for ADHD include counseling, with a particularly focus on behavior management, accommodations in the classroom, addressing coexisting conditions, and medication.
- Additional treatments, including dietary modifications, exercise and meditation, training in study/organizational and executive function skills, and cognitive therapy, in adults warrant further investigation.
- Our increasing recognition of the complexity and uniqueness of each child with ADHD, as well as increasing options for treatment, offer children growing up with ADHD the opportunity to experience success.

CHAPTER 20

Specific Learning Disabilities

Robin P. Church and M.E.B. Lewis

Upon completion of this chapter, the reader will

- Know the historical context for the term *learning disabilities* as well as its definition and implications
- Be aware of key research findings and the biological basis of specific learning disabilities as well as other impairments associated with learning disabilities
- Distinguish among intervention strategies, particularly evidence-based practices used in the assessment and identification of learning disabilities
- Identify the range of outcomes for children and adolescents with learning disabilities
- Recognize the importance of executive function in the diagnosis and treatment of learning disabilities

A great deal of learning involves 1) processing a visual representation of concepts, 2) attaching that perception to language in order to communicate understanding, and 3) demonstrating that understanding with oral or written products. When a child struggles with these subtle and complex perceptual skills, their disabilities in understanding what they are encountering in the classroom impacts their ability to build a “toolbox” for more and more complex learning. This chapter focuses on those children, who represent more than one third of the students identified with disabilities in the United States (National Center for Educational Statistics, 2017;

U.S. Department of Education, Office of Special Education Programs, 2016).

Some historical context is important in understanding learning disabilities. In a 1963 conference organized by parents, Samuel Kirk proposed in his keynote address that the term *learning disabilities* be used for otherwise normally developing students who struggle with reading, writing, or math acquisition. Following the conference, the parents of students with such learning disabilities partnered with parents of students with developmental disabilities to mount a national political effort to get educational services for

The authors would like to acknowledge the contribution of Dr. Virginia W. Berninger in the preparation of this chapter. Her insights and research perspectives enriched our presentation of the growing body of research and practice in this most challenging area of need.

their children. Their efforts resulted in the passage of the Education for All Handicapped Children Act in 1975, also known as Public Law 94-142, which guaranteed the civil right of **free appropriate public education (FAPE)** for students with learning disabilities and developmental disabilities (Johnson & Myklebust, 1967; Kirk & Kirk, 1971; Torgesen, 2004).

The *Diagnostic Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)* (American Psychiatric Association, 2013), is used by medical staff and professionals working in other clinical settings. The *DSM-5* definition of a **learning disorder** (referred to in IDEA 2004 as a specific learning disability, or SLD) is a condition that interferes with the acquisition and use of one or more of the following academic skills: oral language, reading, written language, or mathematics (Clay, 2011; McDonogh, Fanagan, Sy, & Alfonso, 2017). This impairment causes serious difficulties in making daily progress through the general education curriculum at all grade levels. These disorders affect individuals who otherwise demonstrate at least average abilities that are essential for thinking or reasoning. Thus, although intellectual disability, cerebral palsy, seizure disorders, receptive and expressive language disorders, traumatic brain injury, and hearing and vision impairments all can interfere with learning, they are not classified as primary learning disorders.

Recognizing the need for more foundational knowledge to implement FAPE for specific learning disabilities, the 1989 federal Interagency Committee on Learning Disabilities commissioned by the U.S. Congress recommended funding more research on SLDs. This chapter will highlight these findings, which include but are not restricted to the NICHD-funded multi-disciplinary learning disabilities research centers as well as guidelines for applying research findings to practice (Berninger, 2015). In addition, recent research showing that there are multiple types of SLDs is discussed. One important outcome of this research has been a redirection away from a “wait-to-fail” model based on cognitive-achievement discrepancy toward a multi-tiered model of intervention, commonly referred to as response to intervention (RTI) or multitiered systems of support (Vaughn & Fuchs, 2003; Fuchs & Vaughn, 2012; Hughs & Dexter, 2011). This chapter describes learning disabilities not as a single disorder, but as a group of profiles that present differently in different children and need to be fully understood in order for intervention to be effective.

■ ■ ■ CASE STUDY

Noah is a first grader who has been having trouble learning to read. All of the first-grade teachers in his elementary

school provide daily phonological awareness instruction (to help students improve their awareness of phonemes, the sounds that make up syllables and words) for 15 minutes each day during the first 4 months of first grade and daily phonics instruction (teaching students to understand the correspondence between phonemes and written letters and words) for 30 minutes each day during the next 4 months of first grade. This is tier 1 instruction, as part of a 3-tier response to intervention program used by Noah's school to help children with learning problems. During the last 6 weeks of first grade, Noah and his fellow students were individually assessed by the school psychologist on standardized measures of phonological awareness and phonological decoding. This was done by having the students read pseudo words (invented words with plausible English phonology) and then read real words aloud (oral reading). Noah and a number of his peers scored below the 25th percentile on these measures. As such, he was identified as being eligible to receive tier 2 supplementary instruction in second grade in addition to the regular reading program.

Upon entering second grade, Noah received tier 2 supplementary instruction in a small group setting that was provided by trained paraprofessionals. This instruction occurred during regular class time when his classmates were engaged in other kinds of teacher-provided instruction in small groups. Noah's progress was monitored throughout the school year, and at the end of second grade, Noah was again assessed by the school psychologist. His classroom teacher reported that he and several other students who had received tier 2 support were struggling with their written assignments, not just with oral reading. As a result, the psychologist included measures of orthographic awareness (the ability to process and use visual representations of letters and words; e.g., printed words), comprehension, handwriting, spelling, and composition in her assessment along with measures of phonology and decoding. She also reached out to the parents of all the students receiving supplementary reading instruction to obtain developmental, medical, family, and educational histories.

The results of the second-grade RTI assessment were surprising to the teachers and school psychologist. Although most of the 10 children who had received the year of tier 2 supplemental instruction, including Noah, met the RTI criterion for phonological awareness, most did not meet criterion in orthographic awareness (a skill shown in research to be related to handwriting, real word decoding in reading, word encoding in spelling, and composition; Berninger & Richards, 2010). In addition, many of the students still did not meet the RTI criterion for phonological decoding, which requires knowledge and application of correspondences between phonemes (the sounds which compose words) and graphemes (the

written representation of phonemes). The students also exhibited individual differences in whether they did or did not meet the RTI criteria in reading comprehension, handwriting, spelling, and timed composition fluency.

Careful examination of the profiles for these students identified three patterns of difficulty. For the first group of students, the most prominent problem was with **dysgraphia**, characterized by 1) impaired legibility and automaticity of letter production, 2) problems with storing and finding ordered letters in long-term memory, and 3) impairments in executive function for planning serial finger movements. Two students with pure dysgraphia profiles were impaired in handwriting rather than reading, but their illegible, slow, nonautomatic letter retrieval and formation interfered with their ability to complete written activities. Thus, a handwriting disability rather than reading disability accounted for their failure to respond to the tier 1 or tier 2 intervention. None of their parents reported oral language problems during the preschool years.

Noah was in the second group of students, whose main problem was with **dyslexia**, characterized by 1) impaired word decoding (reading) and encoding (writing and spelling), 2) difficulties with phonological coding of heard and spoken words, and 3) problems with **orthographic** coding (processing read and written words and retaining them in working memory). These children also had impairments in the integration of phonological and orthographic processing, resulting in both reading and writing deficits. The five students with dyslexia profiles had difficulty translating written pseudo words into oral pseudo words, written real words into oral real words, and spoken words into written words. Two of them (including Noah) also had co-occurring dysgraphia rather than pure dysgraphia. All of these students had difficulty storing and processing written words in their working memory. Several parents of children with dyslexia, including Noah's parents, reported that their children had difficulties with speech articulation during the preschool years, although their language comprehension always seemed fine.

The third group of students had evidence of an oral and written language learning disability (OWL LD). Their difficulties were characterized by 1) impaired listening and reading comprehension and 2) problems with oral and written expression. The three students with OWL LD had difficulty in syntactic coding (the ability to learn grammar and grammatical relationships), which can interfere with sentence processing during listening and reading comprehension as well as sentence production during oral and written expression. Despite their ability to decode and encode (i.e., sounding out words and spelling), they scored poorly on measures of reading comprehension and written composition.

The school psychologist met with Noah's parents to review the results of these assessments. She explained

that Noah's reading difficulties were not due to impaired intelligence, but to specific problems with decoding that made it difficult for him to decipher and remember new words, and that he also had additional difficulties with writing. Because of his lack of adequate response to tier 1 and tier 2 interventions, he qualified for tier 3 (special education support) under an individualized education plan (IEP; see Chapter 33). He would receive specialized instruction from a special education teacher, and he would also work with an occupational therapist who, together with his teachers, would help him develop improved writing skills.

Thought Questions:

Why do some students respond to targeted intervention whereas others do not? How can schools meet the challenge of providing adequate shared planning time in the school day for true interdisciplinary collaboration?

DEFINING LEARNING DISORDERS

The Individuals with Disabilities Education Improvement Act (IDEA) of 2004 defines a specific learning disability as "a disorder in one or more of the basic psychological processes involved in understanding or in using language, spoken or written, which disorder may manifest in imperfect ability to listen, think, speak, read, write, spell, or do mathematical calculations" (§602[26][a]). The term excludes learning problems that are the result of intellectual disability, emotional disturbance, environmental, cultural, or economic disadvantage, or which are a consequence of visual, hearing, or motor disabilities.

This definition is problematic because it fails to define the core features or origins of SLD as illustrated by the case study about Noah and his classmates. The definition does not identify the "basic psychological processes" of learning or how marked an "imperfect ability" to learn must be in order to constitute a disability. It is a definition of exclusion; all other causes for the learning problems must be eliminated. However, it is clear that SLDs can coexist with other conditions, most notably attention-deficit/hyperactivity disorder (ADHD; McNamara, Vervaeke, & Willoughby, 2008; see Chapter 19). Other disabilities identified in IDEA, however, are excluded from the definition of SLD in order to prevent "double dipping" from existing federal programs that deal with and fund those issues. It is clear, however, that a child with a SLD may also have other conditions that affect learning.

Originally, the common approach for diagnosing SLD was to document a severe discrepancy between ability and achievement by demonstrating a significant difference between the child's potential to learn,

often expressed as an IQ score, and his or her actual educational achievement (Gregg & Scott, 2000). For at least a decade, other diagnostic approaches, such as the Component Model of Reading and RTI, have supported evidence that this discrepancy approach has poor sensitivity, stability, and specificity in discriminating students with specific reading disability (SRD) from those with low IQ scores and poor reading (Aaron, Joshi, Gooden & Bentum, 2008; Francis et al., 2005; Taylor, Miciak, Fletcher, & Francis, 2017). Calculating the discrepancy between cognitive ability and reading or writing achievement may miss diagnosing a SLD such as oral and written language learning disability (OWL LD) because the nature of the disability lowers the ability to answer questions orally posed by the examiner on verbal cognitive ability tests as well as reading comprehension and written expression. Alternatively, the skill that is impaired, such as handwriting in the case of dysgraphia, may be related to processes other than cognitive abilities (Berninger, 2015; Berninger & Richards, 2010; Berninger & Wolf, 2016).

IDEA 2004 expands the means by which SLD can be determined because it states that “a local education agency shall not be required to take into consideration whether a child has a severe discrepancy between achievement and intellectual ability.” It further states that “in determining whether a child has an SLD, a local educational agency may use a process that determines if the child responds to scientific, research-based intervention” (614b, 6, B). This approach, often called RTI, has emerged as common practice.

Planning effective, evidence-based interventions requires an understanding that dyslexia, dysgraphia, dyscalculia (math disability), and OWL LD may be separate or co-occurring deficits within an individual student’s performance profile (Geary, 2004; Kamhi & Catts, 2012; Mazzocco, Feigenson, & Halberda, 2011; Silliman & Berninger, 2014). As illustrated for Noah and his fellow students with learning challenges, an examination of the origin of the learning disability profile can provide an evidence-based direction for effective intervention, whereas the discrepancy model does not.

Response to Intervention

Vaughn and Fuchs (2003) advocated redefining learning disability as an inadequate response to instruction. This response to intervention (RTI) approach has proven to be a promising alternative to traditional testing methods for identifying students with specific learning disabilities (Fuchs & Vaughn, 2012). Important benefits of such an approach include 1) identification of students

using an at-risk rather than a deficit model, 2) earlier identification and intervention, 3) reduction of identification bias, and 4) a strong focus on student outcome. As shown in the case study at the beginning of this chapter, RTI involves the provision of intensive, systematic instruction for a defined period of time to very small groups of students who are at risk for academic failure (see Box 20.1 for more information on RTI).

Three-Tier Models of Intervention The initial step of RTI involves students receiving instruction in their general education classroom, with their progress being carefully and regularly monitored. Those students who do not progress then receive additional services from a learning or reading specialist. Again, their progress is carefully and regularly monitored. Those who still fail to progress are referred for a special education evaluation (Fuchs, Mock, Morgan, & Young, 2003; Olitsky & Nelson, 2003).

In the most commonly used approach to RTI, and the one used by Noah’s school, tier 1 of the model focuses on early intervention based on the National Reading Panel’s recommendation for explicit training in phonological awareness and phonological decoding to prevent reading disabilities (National Institute of Child Health and Human Development, 2000). Tier 2 provides additional supplementary instruction in phonological awareness and phonological decoding for those who do not respond to tier 1 instruction; that is, to improve phonological awareness and phonological decoding. Tier 3 provides comprehensive assessment for those who do not respond to tier 2 instruction to determine if they are eligible for special education services (specialized instruction). Typically tier 1 and tier 2 are delivered by trained paraprofessionals (see Box 20.2 for a description of the paraprofessional’s role), and tier 3 is delivered by both the school psychologist, who carries out the assessment process, and the special educator, who provides specialized instruction.

In the other main model of RTI, tier 1 children are screened for the skills on which they are weak, and early intervention is then provided for those weaknesses. The screens are based on research showing which skills explain significant and unique variance in not only reading achievement, but also writing achievement and listening and oral language skills related to literacy achievement. For example, Puranik, Wagner, Kim, and Lopez were instrumental in promoting the use of phonological awareness and decoding instruction at tier 1 and tier 2, but they also showed the importance of orthographic awareness and writing instruction (Puranik, Wagner, Kim, & Lopez, 2012). The intervention is then tailored to an

BOX 20.1 EVIDENCE-BASED PRACTICE**Response to Intervention**

Response to intervention (RTI) is a multitiered approach to the early identification and support of students with learning and behavioral needs and to closing the achievement gap in at-risk students. The RTI process begins with high-quality instruction and universal screening of all children in the general education classroom.

RTI has also been promoted as an alternative to discrepancy models for identification of students with learning disabilities (Hughes & Dexter, 2011). RTI emphasizes high-quality, scientifically based classroom instruction; ongoing assessment to determine a student's rate of learning; and analysis of these data to determine the level of monitoring and intervention the student needs. The multitiered approach provides increasing levels and intensity of supports. These services may be provided by a variety of personnel, including general education teachers, special educators, and specialists. Progress is closely monitored to assess both the learning rate and level of performance of individual students. Educational decisions about the intensity and duration of interventions are based on individual student response to instruction. RTI is designed for use when making decisions in both general education and special education, creating a well-integrated system of instruction and intervention guided by child outcome data.

For RTI implementation to work well, the following essential components must be implemented with fidelity and in a rigorous manner (Jimmerson, Burns, & VanDerhayden, 2015; McInerney & Elledge, 2013):

- High-quality, scientifically based classroom instruction;
- Ongoing student assessment; and
- Tiered instruction.

BOX 20.2 INTERDISCIPLINARY CARE**The Paraprofessional in the Inclusion Classroom**

Since the late 1990s, the structure of the classroom has changed considerably. With the growing use of the inclusion model in general education classrooms, students with special needs with mild to moderate impairments are included in the classrooms of most general education teachers. Some inclusive settings also provide for students with severe disabilities. The range of abilities, disabilities, and disorders within the classroom community can be extensive, with requirements for both physical and instructional accommodations and modifications. The "teacher's aide" is not a new role, but the need for extensive training and continued professional development has become a priority. These individuals are often among the least trained members of the staff in a school, but when well trained and when offered opportunities for collaboration with teachers and related service providers, they can be important partners in the planning, implementation, and monitoring of instruction in the classroom, including the implementation of RTI. Research indicates that these classroom assistants often work in the area of autism, but there is a need for these partners in other settings as well (Moshe, 2017). They can provide instruction to small groups, provide training and oversight in the use of supportive technologies for students, connect with families, assist in creating materials, and participate in some assessments. Teachers have identified the lack of such support as one of the burdens they feel when implementing an inclusion model, and when paraprofessionals have been trained (along with their supervising teacher partners) and participate in team planning, they feel that their skills improve and they seek continued training opportunities (Walker, Douglas, & Chung, 2017). When the partnership of the professional and paraprofessional is established as a co-teaching model, students benefit.

individual student's relative weakness to personalize their early intervention delivered via "differentiated instruction." RTI is evaluated on the basis of whether individual students improve on the skills for which they have received specialized instruction tailored to their weaknesses. Orthographic skills (e.g., naming and coding letters in memory that correspond to phonemes) are also taught at the tier 1 level because considerable research has documented the contribution of orthographic as well as phonological skills to early literacy (for reviews of evidence, see Berninger & Richards, 2010; Henry, Messer, Luger-Klein, & Crane, 2012; Wandell, & Le, 2017). In addition to oral reading (decoding) skills, handwriting and spelling (encoding) skills are also screened and taught if they are found to be weak. At tier 2, the interdisciplinary team engages in a problem-solving consultation for those students who do not respond at tier 1. The goal is to modify the early intervention by introducing new approaches and developing a plan for evaluating their responses to the modified intervention (Berninger, 2007a, 2007b, 2015). For those students who show persisting struggles in response to the tier 2 intervention, a tier 3 comprehensive assessment is conducted with the goal of making an instructionally relevant differential diagnosis that can then be used to design and implement specialized instruction and evaluate a student's response to it. The goal of all tiers in this version of RTI is personalized education based on carefully tailored, intensive instruction and progress monitoring that informs changes in instruction.

Intensive instruction provided daily in a very small group setting, a key component of RTI, is fiscally demanding in that it may impose a staffing burden on a classroom, especially when carried out in a manner supported by research and policy (Fuchs & Fuchs, 2002; Burns, Jimerson, VanDerHeyden, & Deno 2016). Children who make progress at the end of the prescribed time (usually 12–16 weeks) then return to the general education program, reducing needless referrals for evaluation and potential placement in separate, special learning environments. Children who do not make adequate gains receive a second round of intensive intervention (Gortmaker, Daly, McCurdy, Persampieri, & Hergenrader, 2007; Hay, Elias, Fielding-Barnsley, Homel, & Freibery, 2007). Students who do not benefit from an RTI's first two tiers of instruction signal a need for even more intensive forms of educational intervention (Fuchs, Fuchs, & Vaughn, 2014) and should be referred for comprehensive evaluation to determine the specific services and interventions required. There is also direct evidence that significant and widening differences in reading abilities persist

between students with reading disabilities who receive intensive summer reading instruction and those who do not (Christodoulou et al., 2017).

Despite widespread support for RTI, challenges to implementation remain. These include reliance on an instructional environment that reflects commitment to fidelity, validity, and collaboration; staff preparation; and the availability of teachers who are well trained in all aspects of instruction. By using scientifically derived interventions for early instructional support, the potential for maintaining those students in the general education environment increases. This is in contrast to the discrepancy model, which is a "wait-to-fail" model in which the student may struggle with learning activities until a discrepancy emerges.

This tiered approach has reduced the numbers of students referred to pullout (outside of the general classroom) or special education services (Berkeley, Bender, Peaster, & Saunders, 2009). In research centers around the nation, studies continue to determine how to more effectively implement this model (Deshler, Mellard, Tollefson, & Byrd, 2005; Kennedy & Deshler, 2010; Moss, Lapp, & O'Shea, 2011; Pullen, Tuckwiller, Konod, Maynard, & Coyne, 2010; Ramaswami, 2010). Although most often described as a three-tier model, some schools identify a fourth, or "specialized" tier, which may provide intervention closer to that provided in special education classes without the express referral for a determination of eligibility for special education. Kavale and Spaulding (2008) reviewed the policy implications for these new regulations and concluded that both RTI and psychometric evaluation are appropriate for the identification of children as having learning disorders, allowing them to receive special education services under an individualized education program (IEP).

The diagnosis of SLD is difficult in students identified as English language learners (ELL) or having limited English proficiency. Some of these students may be experiencing difficulty because of their lack of familiarity with English in its academic and/or social use. Alternatively, some may, in fact, have disabilities in learning in both their native language and English (Barrera, 2006; Blanchett, Klingner, & Harry, 2009; Liu, Ortiz, Wilkinson, Robertson, & Kushner, 2008). For these students, technology, including tablets and laptops with appropriate applications based in their native languages, may afford necessary supports (Jozwik & Douglas, 2017). Although teacher preparation for serving students with SLD has expanded, the preparation of teachers to address the needs of students who may have both a learning disorder and English language proficiency issues needs to be improved (Paneque & Barbeta, 2006).

PREVALENCE

The U.S. Department of Education's National Center for Education Statistics (2018) reported that of the more than 6.4 million students receiving special education services during the 2014–2015 school year, approximately 35%, or 2.2 million, were classified as having SLD. The size of this category has nearly tripled since reporting began in 1977. These statistics represent only those students who are served in the public schools and not those who may be served in private, nonpublic, or homeschool environments. A review of a series of NIH-funded epidemiological studies at the Mayo Clinic showed that one in five otherwise typically developing school-age children and youth has an SLD in reading, writing, or math with or without ADHD (Colligan & Katusic, 2015). In addition, some forms of SLD are underidentified. Writing disabilities in particular have been left behind (Katusic, Colligan, Weaver, & Barbaresi, 2009). Specific language impairment (SLI), which is frequently associated with OWL LD, falls under the eligibility category of communication disorders rather than learning disabilities; as a consequence, students with SLI/OWL LD are often underidentified and not treated for their language learning disabilities (Silliman & Berninger, 2014).

Reporting differences among school districts and states also affect the assessment of the prevalence of SLD. Individual school districts exercise considerable autonomy in defining, describing, and coding disabilities at the time services are determined. When families are persistent in seeking special education services and actively involved in the process of attaining those services, the correct and discrete identification of a child's disability is more certain. In districts in which some disabilities are not specified completely, or include other aspects that contribute to learning difficulties, such as attention or behavior problems, an overembracing term such as *multiple disabilities* may be used. This inexact term camouflages the exact nature of a child's problems with learning and may distort the design of an effective and useful education program. However, without more precise definitions and descriptors in the education law, this type of inexact classification by school teams will continue.

The growing number of individuals identified as being on the autism spectrum has also influenced the overall numbers of individuals identified as being in need of special education (see Chapter 18). Many higher functioning students with autism spectrum disorders (ASD) were formerly classified as having learning disabilities. The overlap of severe learning disorders and higher functioning autism has long been

recommended for further study to examine potential links between the two conditions (Williams, Goldstein, Kojkowski, & Minshew, 2008). Although relatively little further research on this has been done, one study (McIntyre et al., 2017) indicates that heterogeneity in reading profiles depends on the level of the ASD. The higher functioning the individual with ASD, the more aligned the profile is to that of an individual with LD. Although this is true of reading profiles, other factors, such as reduced self-regulation of students with ASD, also may have an effect on the independent practice of these skills (Chou, Wehmeyer, Palmer, & Lee, 2017).

The language deficits that may appear in students with SLD or ASD require careful diagnosis and characterization to ensure that interventions can be beneficial and long-term prognosis can be assessed. In a study by Hagberg, Billstedt, Nyden, and Gillberg (2015), adults who had persistent language deficits throughout their school career and into adulthood demonstrated great impairments in daily skills (often with reduced employment) compared with those whose language deficits were only seen in childhood.

ETIOLOGY: BIOLOGICAL AND ENVIRONMENTAL FACTORS

National initiatives such as the Human Genome Project and Decade of the Brain have resulted in an explosion of research on the biological bases of SLDs. Although SLDs and other neurogenetic disorders may share some of the same learning problems at the behavioral level, the underlying genetic and brain bases are not the same as for SLDs such as dysgraphia, dyslexia, OWL LD, and dyscalculia (Berninger, 2015).

Genetics

One reason that not all students respond equally to the same instructional intervention is that the genetic underpinnings are different for language by ear (listening), by mouth (oral expression), by eye (reading), and by hand (written expression). Since the late 1990s, substantial progress has been made in understanding the genetic bases of specific reading disabilities including dyslexia and other language-related SLDs (e.g., Fisher & DeFries, 2002; Olson, Wise, Connors, Rack, & Fulker, 1989; Olson et al., 2013). For example, twin studies have documented both genetic and environmental influences on specific reading disabilities in otherwise typically developing individuals, and unique genetic contributions remain even after students respond to early intervention (Samuelsson et al., 2008). Linkage

studies and gene candidate studies have identified relationships between locations in the human genome and specific phenotypes (i.e., behavioral markers of genetic variables). Specific genes may influence response to instruction, and while results for linkage analysis and gene candidate studies have been replicated across multiple research groups, the findings indicate that the genetic bases for specific reading disability are heterogeneous, meaning that multiple gene candidates may underlie the same phenotypic expression. Thus, individuals may differ in the genetic basis for the same observable behavioral difficulties in language learning. This serves to emphasize the complex nature of reading and reading disability.

Research using genetic linkage and association techniques has shown a relationship among specific reading disabilities such as dyslexia and loci on chromosomes 1, 2, 3, 6, 15, and 18 (Raskind, Peter, Richards, Eckert, & Berninger, 2012; Scerri & Schulte-Körne, 2010). The genetic basis of math disabilities has also been studied (Berninger, 2015). In a twin study in which one twin had math disability and the other did not, higher rates of dyscalculia were found in identical than in fraternal twins (Cohen, Kadosh, & Walsh, 2007). There is also evidence that molecular markers differ across dysgraphia, dyslexia, OWL LD, and typical language learners (Abbott, Raskind, Matsushita, Richards, Price, & Berninger, 2017).

Epigenetics research (Cassiday, 2009) is underway that shows that genetic expression at the observable, behavioral level can respond to environmental interaction and input (see Chapter 1). Thus, although genetic anomalies may contribute to the etiology of a SLD at the biological level, the most effective treatment may be environmental (i.e., educational programming). For example, in one study, students with dysgraphia, dyslexia, and OWL LD who completed a special curriculum of computerized instruction showed significant improvement on the biologic impairments associated with their diagnosed SLD (Tanimoto, Thompson, Berninger, Nagy, & Abbott, 2017).

Brain Imaging

Since the Decade of the Brain that began in 1990, there has been an explosion of knowledge about the brain correlates of language and math. A variety of non-invasive imaging methodologies that are safe to use with developing children and youth have been used in research (see Chapter 8). Initially, these studies focused on documenting differences in brain structure and function between typically developing language or math learners and those with an SLD such as dyslexia

(e.g., Sandak, Mencl, Frost, & Pugh, 2004; Simos et al., 2002; Turkeltaub, Gareau, Flowers, Zeffiro, & Eden, 2003) or dyscalculia (e.g., Cohen et al., 2007; Dehaene & Cohen, 1995). Subsequent imaging studies have shown how the brain changes in RTI (Berninger & Dunn, 2012; Berninger & Richards, 2010; Gabrieli, 2009) and addressed the issue of whether the brain of students with a SLD, such as SRD, normalized after intervention. Considerable evidence across many research groups now supports the contention that the brain can normalize in response to instruction. One imaging study in particular demonstrated that the brains of students of lower socioeconomic backgrounds are especially responsive to reading interventions (Romeo et al., 2017). This finding is important because SLDs occur in all socioeconomic groups and have a particular impact in children and youth from low-income families who are especially vulnerable to the long-term consequences of SLDs. Understanding brain differences in students with reading disability may also help parents and educators select the best remediation strategy (Wandell & Le, 2017).

CLASSIFYING LEARNING DISORDERS

The section that follows explains and analyzes learning disorders across three classifications: specific reading disability, specific math disability, and specific writing disability.

Specific Reading Disability

SRD, also called developmental dyslexia, is by far the most commonly recognized form of learning disability, accounting for over one third of the special education population (National Center for Educational Statistics, 2017). Theoretically, any defect in the processing or interpretation of written words can lead to a diagnosis of SRD. Efficient reading depends on rapidly, accurately, and fluently decoding and recognizing the phonemes of single words (Talcott et al., 2000; Wolf, Bowers, & Biddle, 2000). Phonological awareness includes 1) phoneme awareness (the understanding that speech is made up of discrete sounds), 2) a metacognitive understanding of word boundaries within spoken sentences, 3) a recognition of syllable boundaries within spoken words, and 4) an ability to isolate these phonemes and establish their location within syllables and words. Phonological awareness manifests in the ability to analyze and manipulate sounds within syllables (e.g., to count, delete, and reorder them). As a child learns to read, specialized areas of the brain and its structures are trained to associate text with the sounds of language (Wandell & Le, 2017). If a child

does not realize that syllables and words are composed of phonemes and that these segments can be divided according to their acoustic boundaries, reading will be slow, labored, and inaccurate; in addition, comprehension will be poor. A second possible mechanism may be a defect in phonetic representation in working memory, wherein the child can understand the syntactic structure of a sentence but is unable to maintain it in working memory long enough to comprehend the meaning (Kamil, Pearson, Moje, & Afflerbach, 2010; Mann, 1994).

Poor reading has been linked to phonological processing impairments, but these impairments alone are not sufficient to explain SRD. Wolf and Bowers (1999) proposed three underlying types of specific reading disability: 1) phonological impairment, in which the reader attempts to manage the connection of sound to symbol accurately; 2) disrupted orthographic processing, which results from slow naming speed and influences the acquisition of fluency in both familiar and unfamiliar content; and 3) a combination of both impairments. Individuals who manifest the double impairment, phonological impairments and naming speed impairments, are the poorest readers. This hypothesis has not been universally accepted. Some researchers failed to find a phonological impairment in the absence of a naming-speed impairment and noted that the double-impairment groupings identified individuals with different neuropsychological profiles (Cirino, Israelian, Morris, & Morris, 2005; Waber, Forbes, Wolff, & Weiler, 2004). Others have found little support for the theory that underlies the double-impairment hypothesis, namely that rapid serial processing and temporal integration of letter identities are the primary means by which orthographic codes are formed (Ritchey & Goeke, 2006; Vellutino, Fletcher, Snowling, & Scanlon, 2004; Vukovic & Siegel, 2006). They also question the independence of phonological and rapid naming skills and the specificity of impairments in rapid naming for reading.

The Neural Substrates of Reading Reading is a dynamic process that develops with age and experience. It encompasses a wide variety of skills that develops at varying times. Early instruction focuses on learning to read and targets decoding. Later instruction uses reading to learn, and the focus shifts to comprehension. Beginning, inexperienced readers are focused on decoding and employ a “bottom-up” approach that uses analytic and synthetic processes. They are more focused on sounding out each word they encounter, which can often hinder comprehension. Experienced readers use a “top-down” approach that results in faster, more efficient reading. These readers use context

and word recognition to gain meaning. Top-down, or conceptual, approaches assume that the path from text to meaning extends from prior knowledge that is applied to the process of acquiring the sound-symbol connection of reading.

Compensated poor readers recruit additional brain areas to read. Neuroimaging studies in individuals with dyslexia show reduced engagement of the left temporo-parietal cortex for phonological processing of print, altered white matter connectivity, and functional plasticity associated with effective intervention (Fisher & DeFries, 2002; Gabrieli, 2009). Posterior brain systems predominate during early reading acquisition (Simos et al., 2002; Turkeltaub et al., 2003). As individuals become older and are more skilled at reading, they begin to engage parietal and superior temporal areas, with frontal regions coming online last. Individuals who are identified as having dyslexia do not increase activation of the word form area (located in the left occipitotemporal gyrus) even after repeated trials of word exposure. As they grow older, children show the opposite—activation of the anterior system. Anterior activation is not the sole processing difference, however, as individuals with dyslexia also activate their right anterior inferior frontal gyrus as well as the right posterior occipital-temporal region (Sandak et al., 2004). In other words, individuals with dyslexia show abnormalities in brain processing during reading.

Shaywitz and colleagues (2004) have underscored the importance of dysfunction of the left hemisphere brain systems in SRD. They provided a year of intensive reading remediation to a group of individuals with SRD. After the intervention, the individuals made gains in reading fluency, and neuroimaging studies showed increased activation of the anterior and dorsal systems. Another study in adults with a lifetime history of SRD demonstrated that reading remediation in older individuals might be different. This study showed increases in both left and right hemisphere activation following successful reading intervention (Eden et al., 2004).

Specific Math Disability

Specific math disability, also known as dyscalculia, is a complex phenomenon that must be considered in the context of other learning processes and impairments. Three to six percent of individuals have a performance on tests of mathematical ability that is discrepant from their IQ scores (Mazzocco, 2007; Shalev & Gross-Tsur, 2001). This percentage may be higher than the true frequency of a learning disorder in mathematics. Poor performance may be due to a lack of adequate instruction in areas that are covered by the assessment measures.

Another reason for discrepant performance on math tests may relate to impairments in reading or executive function rather than mathematics (Dirks, Spyer, van Lieshout, & de Sonnaville, 2008; Donlan, 2007; Jordan, 2007).

Math disability is commonly seen in the presence of other learning and cognitive disorders. Of individuals with a math disability, approximately 17% have been found to have coexisting SRD and 26% have ADHD (Gersten, Jordan, & Flojo, 2005; Shalev & Gross-Tsur, 2001). In another study that focused on kindergarteners with developmental language disorders, 26% had significantly impaired arithmetic skills (Manor, Shalev, Joseph, & Gross-Tsur, 2001). In addition, Marshall, Schafer, O'Donnell, Elliott, and Handwerk (1999) found that inattention exerts a specific and deleterious effect on the acquisition of arithmetic computation skills. This has led some to defer the diagnosis of math disability in the presence of ADHD until the ADHD is properly managed (Shalev & Gross-Tsur, 2001). Finally, assessment of mathematics encompasses a variety of skills and neuropsychological processes, some of which may be impaired whereas others are relatively spared.

Difficulty with mathematics may manifest in different ways. Counting, basic calculation, problem solving, place values (base-10 concepts), equivalence, measurement, time, relations (as in algebra), and geometry are but some of the ways that mathematics is expressed. Despite the wide range of expression, math disability is specifically defined by deficiencies in fact mastery and calculation fluency (Jordan, Hanich, & Kaplan, 2003). Some of the difficulties that children encounter in mathematics evolve from their earliest encounters with numbers; that is, their number sense and early numeracy. The intuitive understanding of numbers and related concepts such as how numbers grow and diminish with calculation may be viewed as having a parallel to the initial reading skill of phonemic awareness, which includes the earliest awareness of how words are made up of discrete sounds. Research has shown that this initial "gut sense" about numbers may be significant in identifying the origins of math disability (Mazzocco et al., 2011).

Math disability evolves over time. Early presentations exhibit difficulty with retrieval of basic math facts and in computing arithmetic exercises. These have been related to immature counting skills. Older individuals have difficulty in learning arithmetic tables and comprehending the algorithms of adding, subtracting, multiplying, and dividing. These manifest as misuse of signs, forgetting to carry, misplacing digits, or approaching problems from left to right (Shalev, 2004). In another study, 10 to 11 year olds with math

disability showed persistently poor math performance on reexamination 6 years later (Shalev et al., 2005).

Visuospatial working memory deficits are often present in those identified with math disability. A broad view of the connection of cognitive, neurobiological, and developmental components is needed, since these elements change throughout development and can create a vulnerability if not recognized (Menon, 2016).

The Neurobiology of Math Neurobiological evidence of math disability is still evolving, and the exact mechanism remains to be delineated. Evidence derived from clinical syndromes, neuroimaging, and genetics suggests a number of brain-based impairments. Although the clinical syndromes point to a major role of the parietal lobe in dyscalculia, the relationship is not simple. Different types of mathematic skills require coordination of different brain functions and, by extension, activation of different brain areas. Complicating this is the finding that people who have difficulty with math will recruit other brain areas and use other psychological mechanisms to compensate for the impairment in brain function.

There is a paucity of studies that focus on the genetics of math disability. Yet, familial occurrences of the disorder have been described. Shalev and Gross-Tsur (2001) found that approximately half of siblings of individuals with math disability also had evidence of math disability. In a study of twins, one of whom had math disability, significantly higher rates of dyscalculia were found in identical twins than in fraternal twins (Cohen et al., 2007).

Several psychological mechanisms have been proposed for math disability. In early research, Rourke and Finlayson (1978) found that individuals with math disability alone showed poor nonverbal skills (visual-spatial and tactile-perceptual), whereas individuals with combined math disability and SRD showed poorer verbal skills (verbal and auditory-perceptual). Geary (2004) has posited three subtypes of math disability based on memory and cognitive impairments: 1) the procedural subtype, 2) the semantic memory subtype, and 3) the visuospatial subtype. Others have associated math disability with executive function and working memory impairments (McLean & Hitch, 1999). Dehaene and Cohen (1995) advocated a "triple-code model" wherein simple arithmetic operations are processed by the verbal system within the left hemisphere and more complex arithmetic procedures that require **subitization** (the ability to perceive at a glance the number of items presented), **cardinality** (the ability to perceive the number of elements in a set or other

grouping), and visual representations are bilaterally localized in the brain.

Specific Writing Disability

Specific writing disability, also known as dysgraphia, is a multifaceted and complex deficiency involving the effective and coherent processing of information and transcribing it into written form. Writing is a psychomotor process involving the motor and spatial processes of handwriting, the orthographic coding of letters and symbols, storing and retrieving words, and correct spelling and syntax. In most cases, this deficit occurs together with other developmental disabilities (most commonly dyslexia, attention deficits, and ASD).

Writing difficulties are usually discovered when children are asked to produce written work that demonstrates their progress with reading and requires participation in discussions of subjects learned. Students who become frustrated with the writing process sometimes show fatigue, disengagement, or simply stop writing.

There are stages of writing acquisition that must be understood in order to diagnose the actual origin of the problem—linguistic or motoric. Linguistically, an individual takes in the phonemic and visual components of words and then applies remembered spelling, grammar, and meaning to get the word on paper in a comprehensible format. Motorically, the individual must manage the instrument for writing while remembering and planning the sequence needed to represent letters and other symbols in a defined space (Prunty & Barnett, 2017). Although there is usually a primary cause for the dysgraphia, a student may exhibit both motoric and linguistic symptoms.

The subtypes of specific writing disability are dyslexic dysgraphia, motor dysgraphia, and spatial dysgraphia. Dyslexic dysgraphia is most often seen as illegibility of spontaneously created work; however, given time and a model, copied work improves. Motor dysgraphia stems from poor fine motor control or lack of dexterity. Although copied or spontaneously written material may start out neat and conforming to space, it degrades in longer writing samples (Graham, Collins, & Rigby-Wills, 2017). Sustaining the coordination for the task seems to be a problem. Spatial dysgraphia impacts drawing as well as writing due to the fact that the individual does not perceive space accurately. Written products, both copied and original, are illegible and spread beyond the defined space provided for the task.

Essentially, specific writing disabilities stem from deficits in automatically remembering and mastering

the sequences for managing the orthographic “loop”—coding the units of language formation (morphemes, phonemes, and syntax), motor control, sustaining and focusing attention, and self-monitoring production (Berninger & Wolf, 2016).

The Neurobiology of Writing The angular gyrus plays a role in mediating complex language functions, and it connects sensory experiences like touch to spatio-visual experiences that allow recognition of subtle visual distinctions (such as the differences among letters like *g*, *b*, *d*, *p*, and *q*) or punctuation. This ability to note salient features connects to the ability to sustain attention (Nicolson & Fawcett, 2011).

Attention and memory, as executive functions, call on the prefrontal cortex to coordinate the process to allow the student to remember the task assigned, the relevant ideas related to the task, and the organization required to assemble the response to the task orthographically. An area in the middle frontal gyrus (BA6), termed the “graphemic/motor frontal area,” supports bridging between orthography and motor programs specific to handwriting (Roux et al., 2009).

IMPAIRMENTS ASSOCIATED WITH SPECIFIC LEARNING DISABILITIES

One quarter to one half of individuals with learning disorders have additional impairments that interfere with school functioning. These may include executive function impairments, ADHD, social cognition impairments, and emotional and behavior disorders. These behavior and emotional problems may be externalizing (e.g., aggression, oppositional-defiant disorder, or conduct disorder) or internalizing (e.g., shyness, depression, or anxiety). Failure to detect and treat these additional impairments is a common reason for failed intervention programs. As comorbid conditions may adversely affect outcome, it may be most appropriate to categorize individuals not only on the basis of their learning impairments, but also according to comorbid conditions.

Memory Impairments

Impairments in the ability to listen, remember, and repeat auditory stimuli have been associated with reading disability. The holding of information in immediate and working memory is essential in learning to read (Berninger & Swanson, 2017). Research shows that children with learning disabilities have deficits in working memory (Peng & Fuchs, 2016) that can affect reading

and math performance. Attention components in working memory include 1) focused attention (inhibiting irrelevant information), 2) switching attention (moving from one relevant stimuli to another), 3) sustaining attention over time (maintaining on task behavior), and 4) self-monitoring (having awareness of whether or not you are on task). These contribute uniquely to reading and writing achievement (Berninger & Richards, 2010). A number of studies comparing individuals with equivalent IQ scores but low or high reading abilities have reported impairments in the poor readers on the Digit Span subtest of the Wechsler Intelligence Scale for Children–Fourth Edition (D'Angiulli & Siegel, 2003; Wechsler, 2003). Executive dysfunction coupled with memory impairments may adversely affect a student's ability to choose the appropriate strategy for solving a problem. Working memory, which is based in the area of the prefrontal cortex concerned with short term management of memory and attention, has also been studied and found to be of particular interest (Schuchardt, Maehler, & Hasselhorn, 2008). As a result, the student's ability to use cognitive behavioral techniques may be limited because he or she cannot remember a sequence of problem-solving steps.

Impairments in Executive Functions

According to Pennington (1991), executive functions (see Chapter 13) involve the ability to maintain an appropriate problem-solving set of procedures for attaining a future goal. This includes the ability to 1) inhibit or defer a response; 2) formulate a sequential, strategic plan of action; and 3) encode relevant information in memory for future use. These metacognitive abilities are necessary for organizational skills, planning, future-oriented behavior, maintaining an appropriate problem-solving set of procedures, impulse control, selective attention, vigilance, inhibition, and creativity in thinking. These abilities involve an awareness of what skills, strategies, and resources are needed to perform a task effectively. They also require the ability to use self-regulatory mechanisms to ensure the successful completion of a task, yet students with learning disorders are often impulsive rather than reflective when presented with a problem-solving task. This failure to consider alternative solutions often results in errors or a poor quality solution. Executive functions become essential beginning in Grade 4 in order to complete homework and long-term projects, to sustain attention during lectures, and to set future goals (Berninger, Abbott, & Cook, 2017). Disruption in this organization and control of behavior often manifests as disruption in the classroom. Executive function impairments are also a key feature in ADHD.

Attention-Deficit/Hyperactivity Disorder

Approximately one half of individuals with learning disorders meet criteria for the diagnosis of ADHD, making this the most common comorbid diagnosis. Studies have found that the prevalence of ADHD in individuals with learning disorders is higher than the prevalence of learning disorders in individuals with ADHD (Friedman, Rapport, Orban, Eckrich, & Calub, 2017; Friedman, Rapport, Raiker, Orban, & Eckrich, 2017). The symptoms typically include inattention, impulsivity, and hyperactivity (see Chapter 19). Recent research reviews indicate that the increase in this identified comorbidity may be due to inclusion of students with writing disorders who were previously under-identified relative to students with reading and math disorders (DuPaul, Gormley, & Laracy, 2013).

Impairments in Social Cognition

Impairments in social cognition are noted often in individuals with learning disorders (Bauminger, Edelsztein, & Morash, 2005; Bauminger & Kimhi-Kind, 2008). Such individuals have difficulty understanding complex emotions, tend to be socially isolated, may have few close friends, and infrequently participate in social activities. In turn, they are often overlooked or rejected by their peers because of their odd behavior and poor school or athletic performance. Teachers tend to rate these individuals as having social adjustment difficulties and as being easily led. There may be many reasons for these problems, including poor social comprehension, inability to take the perspective of others, poor pragmatic language skills, an inability to recognize facial expressions, and misinterpretation of body language. This awareness of the intent or perspective of others is called *theory of mind* (see Chapter 18 for a discussion of theory of mind as it relates to ASD) and sheds light on how individuals develop the means to understand the social cues sent by others so that they may develop their own awareness of social situations and form appropriate responses (Bloom & Heath, 2010; Schneider, 2008). The reported prevalence of ASD has increased significantly since 2000, when the CDC reported occurrence of one in 150 children, to 2014, when the occurrence was reported to be one in 59 children. The child who has a combination of a learning disorder, poor pragmatic language skills, executive function impairments, and impairments in social cognition may be difficult to distinguish from a child who falls on the autism spectrum. It is likely that these conditions will be more closely linked in the future (McIntyre et al., 2017) and may have common genetic and neurobiologic signatures.

Emotional and Behavioral Disorders

Although associated emotional and behavioral impairments may represent endogenous biological conditions, they also may result from the child's experiences of school failure. Although individuals with learning disorders may exhibit conduct disorders, withdrawal, poor self-esteem, and depression, related therapeutic services to address these concomitant disorders are not mandated in federal law. A secondary diagnosis of an emotional disability would have to be in evidence in the student's profile in order for services to be provided to address both the learning disability and related social/emotional responses to the challenges in learning. These individuals are less likely to take pride in their successes and more likely to be overcome by their failures. More than one third of students with learning disorders receive a failing grade in one or more courses each school year. These individuals often exhibit chronic frustration and anxiety (Nielsen et al., in press) as they attempt to meet the demands of skill-based tasks, such as phonological decoding, comprehension, spelling, and math. This school failure, combined with social skills impairments, may lead to peer rejection, poor self-image, and withdrawal from participation in school activities (Abbott et al., 2017; Maag & Reid, 2006). Eventually, these individuals may avoid going to school all together or act out in class in order to obtain the attention they do not receive through good grades. There is a lack of agreement regarding how to best serve students with coexisting emotional/behavioral disorders and SLD, with some experts pointing out that the design of inclusion may exacerbate inner conflicts and frustrations, requiring consideration of more specialized learning settings (Eller, Fisher, Gilchrist, Rozman, & Shockney, 2015). In the United States, the overall dropout rate for individuals with SLD is three times that of all students. In the 2013–2014 school year, 18% of students with SLD dropped out as compared with 6.5% of students overall. Although the dropout rate has decreased since the late 2000s, it remains unacceptably high. During this time period almost half a million students with SLD left high school without a diploma, putting them at high risk for a poor outcome in transitioning to meaningful employment (National Center for Learning Disabilities, 2017).

HEALTH PROBLEMS SIMULATING SPECIFIC LEARNING DISABILITIES

Some individuals who do not have learning disorders may demonstrate learning differences in school as a consequence of another developmental disability, a

chronic illness, or psychosocial problems. If these individuals are misdiagnosed as having an SLD, efforts directed solely at treating the learning problem will have limited success. Instead, the underlying problem must be identified and addressed. Once this problem has been treated, the learning problem may well improve or disappear.

For example, if a child has an unidentified sensory impairment, learning is likely to be affected. The provision of hearing aids to a child with hearing loss or of glasses to the child with a refractive error may lead to a significant improvement in school performance (see Chapters 25 and 26). Individuals with epilepsy (see Chapter 22) also may have problems in school resulting either from poorly controlled seizures or from side effects of antiepileptic medication. Modifying the drug regimen may significantly improve both attention and learning. Individuals with psychiatric disorders (see Chapter 27) also may fail in school. The use of psychotropic drugs and psychotherapy, including cognitive behavior therapy (see Chapter 34), often leads to significantly improved school performance, although some of these drugs can have an adverse effect on attention. (For specific information on medication side effects, see Appendix C.)

An increased incidence of learning problems also has been described in individuals with chronic illnesses, such as diabetes, HIV infection, sickle cell disease, cancer, and chronic kidney and liver disease (see Chapter 24). In these situations, a learning disability may exist, but learning difficulties also may result from other causes such as illness, excessive school absences, attention impairments, or depression. A secondary learning problem rather than a learning disability is suggested if learning improves once the medical condition is brought under control (Sexson & Madan-Swain, 1993).

Individuals who were born prematurely have an increased incidence of learning disorders. Acute disorders such as meningitis, encephalitis, and traumatic brain injury (TBI) also can result in the subsequent development of learning problems. Mild TBI is the most common of these and is an increasingly recognized cause of behavior and learning problems in individuals (see Chapter 23). The injury may result in either temporary or permanent neurological impairments. Affected individuals present special challenges in the classroom as a result of the evolving nature of their recovery (Carney & Porter, 2009). During the acute phase, disorders of attention and other executive functions, higher language skills, and behavior are common. Because of this, TBI has been identified as a separate category of disability under IDEA 2004 (see Chapter 33) to distinguish it from specific learning disabilities and other

related disorders. However, when recovery is completed, some individuals with TBI may have a residual learning disorder.

Finally, psychosocial influences may affect the child's ability to learn. A child who is hungry cannot pay attention or learn well. A child who comes from a home that does not value learning is at high risk for underachievement in school. A home beset with family problems or abuse is a poor setting in which to encourage the child's school performance. Improvement in these psychosocial areas would likely result in improved school performance but has proven difficult to achieve. Until a complete picture of why students in a particular school are identified as having profiles of underachievement—and until the role of factors such as poverty, prematurity, nutrition, and environmental threats (e.g., lead poisoning and other environmental toxins) are fully understood and addressed—educators will continue to struggle to reconcile disorders of learning and effective instructional practices (see Chapter 42).

What is vital to the improvement of this state of affairs is greater attention to how school teams obtain and use information that identifies learning disabilities and how resources are mobilized to treat the learning disabilities in the school, school district, and community. All existing information should be used in the educational process. Medical and educational assessments by qualified examiners, combined with the assessment data developed by the school, serve as the foundation for developing an effective educational program, which optimizes the use of related services such as speech-language therapy or support from learning specialists in a collaborative effort to serve the student within the most inclusive setting possible (see Chapter 33).

ADDITIONAL CHALLENGES IN THE SCHOOL SETTING

There is a disproportionality of representation of students from various racial and ethnic subgroups in special education (see Chapter 42). This has been linked to gaps in achievement, resulting in the overidentification of these students (Williams, Bryant-Mallory, Coleman, Gottel, & Hall, 2017). Schools serving students with an array of special needs must also consider two additional factors that complicate effective instruction and intervention—the growing number of English language learners and the impact of poverty in some school settings. Roughly 9.4% of students in public school are identified as ELLs (National Center for Educational Statistics, 2017), and of that group, nearly 10% are also identified as having disabilities (Liu, Ward, Thurlow, &

Christensen, 2017). This requires attention to accurate assessment of abilities and disabilities so that appropriate intervention to support these students can be provided (Kim & Helphinstine, 2017). This appropriate determination of need will lead to a greater number of students with cultural and linguistic diversity being accurately placed within the inclusive instructional setting (Barrio, 2015; Driver & Powell, 2017).

Poverty and the related factor of homelessness also complicate identifying and serving students, especially when they have learning disabilities. The Condition of Education 2017, a congressionally mandated annual report summarizing the latest data on education in the United States, reports that nearly 20% of children under the age of 18 live in poverty and that 2.5% of the public school population is homeless. This includes students in both urban and rural settings (Barrio, 2017). Because homelessness is closely related to mobility, many children in poverty are moving around so much that accurate assessment of their needs is not possible. Others already identified as needing services often do not receive them due to limited access to records and/or the availability of qualified educators and other specialized providers.

ASSESSMENT PROCEDURES

The assessments used to identify students with an SLD consist of individually administered tests designed to reveal both strengths and challenges so that comprehensive recommendations can be made. A school team, including the parent and student (when appropriate), reviews all assessments and determines the appropriate level of services required to accommodate the student's learning needs. These recommendations are written into the individual education program (IEP) with explicit, measurable goals and objectives, as well as the clear description of how progress will be evaluated (see Chapter 33). Recommendations may include specific programmatic interventions in reading, writing, or mathematics; grouping strategies; or even additional therapeutic interventions from specialists (Fletcher, Lyon, Fuchs, & Barnes, 2007).

The No Child Left Behind (NCLB) Act of 2001 (PL 107-110) has been replaced by the Every Student Succeeds Act of 2015 (PL 114-95; the reauthorization of the Elementary and Secondary Education Act of 1965; see Chapter 33), but the continued emphasis on access to the general education curriculum and high stakes testing as a measure of mastery creates challenges for students with SLD. There have been some victories for families around issues of accommodations and modifications used in instruction and for high stakes testing, but these battles continue to occur.

Psychological, language, and educational tests are the mainstay of assessment in school-age individuals (see Chapter 13). However, a complete medical, behavioral, educational, and social history also should be taken in order to consider confounding variables that may simulate, mask, or worsen a learning disorder (Francis et al., 2005; Lyon, Shaywitz, & Shaywitz, 2003). Simply looking at the discrepancy between potential and actual achievement can lead to misclassification of the students' needs. Evaluators need to use procedures for assessment that provide more information than a simple statistic as an indicator of a student's abilities (Grigorenko, 2009). Global standardized assessment tools, such as IQ tests, are not sensitive enough to allow an instructional program to be tailored to ensure a student's academic growth. Standardized proficiency testing must be combined with authentic assessment, norm-referenced as well as criterion-referenced tests, informal assessment, and portfolio assessment (based on a collection of artifacts that represent the student's work product) to obtain the full picture of how the student is progressing. This permits connecting and applying this information to the content the student is learning. If this does not occur, inappropriate treatment recommendations can result. Labeling a test taker as a "low achiever" does no service to the student. Well-documented strengths and challenges lead to a more serviceable IEP (Liu et al., 2016; Phipps & Beaujean, 2016).

Continued periodic assessment of progress in the class is also required. This periodic "snapshot" of achievement allows the effectiveness of the program to be evaluated and the instructional program to be adjusted. Periodic reassessment of cognitive and executive functions is warranted if the student is failing to progress. In addition, annual assessment of academic subjects is important to determine the progress the child has made and the effectiveness of the program. This aligns with the purpose of RTI as well as the mandates for progress monitoring.

INTERVENTION STRATEGIES

The practice of inclusion has placed most students with learning disabilities into general education classrooms where they have access to the general education curriculum with modifications, accommodations, and supports (see Chapter 33). As a result, interventions and strategies specifically designed for learning disabilities are now embedded into some general education classroom through the Universal Design for Learning (UDL; King-Sears, 2014). UDL provides multiple modes of presentation with a variety of potential responses so that teachers can modify the material for

all students. Additionally, computer-assisted instruction (CAI), small group specialized methods, and individual tutoring are now provided within the general education classroom. When available, a special education teacher will collaborate with the general educator to recommend specific strategies or to co-teach certain lessons. The use of evidence-based practices (EBPs) in the general education classroom promise to close the achievement gap for low-performing students, but while gains have been reported, they may be difficult to sustain over time (Fuchs et al., 2015).

The primary goal of intervention is to facilitate the acquisition and expression of the knowledge needed for effective performance in school and subsequently in the workplace. The objectives are to achieve academic competence, treat associated impairments, and prevent adverse mental health outcomes. This requires the cooperation of educators, health care professionals, and families. If individuals with SRD are not provided with an early intervention program composed of instruction in phonological awareness, sound-symbol relations, and contextual reading skills before the third grade, at least three fourths of these students will show little improvement in reading throughout their later school years (Shaywitz & Shaywitz, 2005).

In addition to treating the core learning disorder, intervention strategies need to focus on associated cognitive, attention, language, perceptual, and sensory impairments. Immaturity, lack of motivation, and poor impulse control also must be considered in determining the child's needs for remediation (Bakker, Van Strien, Licht, & Smit-Glaude, 2007). An intervention must recognize the developmental changes that occur as a student gets older. It must be sensitive to the changing demands of the curriculum, the typical developmental challenges faced by the child, and the effects of maturation and intervention on the academic abilities of the student. In addition, successful interventions must not be withdrawn prematurely because of the positive impact they have on developing the self-awareness and self-advocacy skills necessary to combat stigma, to build self-confidence, and to access services and supports in postsecondary school settings or the workplace (Reschly, 2008).

Professionals continue to debate the most effective intervention strategies. A major consideration is whether to teach to the child's abilities (i.e., compensation/circumvention strategies) or the disabilities (i.e., remedial strategies; Liu et al., 2016; Phipps & Beaujean, 2016). Little evidence supports the superiority of one approach over the other. It is generally agreed, however, that there must be a combination of instructional and cognitive interventions (Alexander & Slinger-Constant, 2004).

Instructional Interventions

The following is a review of some interventions in reading, writing, mathematics, and other areas.

Reading In 2000, the National Reading Panel released its report on research-based reading instruction (National Institute of Child Health and Human Development, 2000). The panel identified the following six essential components to a sound reading program: 1) phonemic awareness; 2) phonics skills; 3) fluency, accuracy, speed, and expression; 4) reading comprehension strategies to enhance understanding; 5) teacher education; and 6) computer technology. Once decoding is unlocked, students are able to use these skills to build fluency. The focus can then shift to interventions that support and develop the expansion of vocabulary (for general communication, usage, and technical use) and enhance comprehension. Most states maintain a list of approved evidence-based practices that teachers may draw from in choosing specific interventions. These EBP's are not uniform and vary not only from state to state, but even within different school systems within each state.

Reading proficiency depends on phonological processing and alphabetical mapping. Phonics instruction, however, is different from phonological awareness training (Shaywitz, 2005). Clark and Uhry (1995) defined phonics as a low level of rote knowledge of the association between letters and sounds. Phonological awareness, on the other hand, includes higher level metacognitive understandings of word boundaries within spoken sentences, of syllable boundaries in spoken words, and of how to isolate the phonemes and establish their location within syllables and words. Regardless of the method chosen, the major goal of reading instruction is to improve phonological awareness (the sublexical aspect of reading) so that there is effective word recognition and comprehension of meaning (the lexical aspect of reading). Reading activities focus on helping a child gain print awareness and become attuned to the sound characteristics of language (phoneme awareness) and letter-sound relationships (the alphabetic principle).

Reading instruction in elementary school varies significantly and is influenced by regulation, policy, and budget. The common thread to this instruction includes methods designed to increase skills in acquiring vocabulary, using syntax, and understanding meaning (Alexander & Slinger-Constant, 2004; Schatschneider & Torgesen, 2004). While there is no single model of reading instruction that suffices for all individuals, there are certain components that all agree are essential for good instruction (National Institute of Child Health and Human Development, 2000). In the

final analysis, semantic (the meaning of words), syntactic (the rules that govern the ways words combine to form phrases), and graphophonemic (using combined letters and sounds to decode words) systems must be united for successful reading.

Along with knowledge of phonics, efficient reading requires a rapid sight vocabulary (words recognized on sight without sounding them out phonetically). Different word recognition strategies include analysis of sound (phonics or phonetics), analysis for structure (visual configuration), and use of memory skills to recognize words as total entities (whole-word approach). Comprehension strategies center on developing the ability to draw meaning from text and to read fluently. Stevens, Walker, and Vaughn (2016) have provided a synthesis of research showing that repeated reading increases oral reading fluency in students who are competent decoders but need practice in faster, more accurate reading. Multicomponent interventions and assisted reading with audiobooks produced gains in fluency and comprehension and found that repeated reading is still the most effective intervention for improving fluency in students with learning disabilities.

Many students with a reading disability need an adjustment in the curriculum. Some methods of teaching reading, such as Orton-Gillingham, Wilson, and Lindamood Bell, employ multisensory approaches (Birsh, 2011; Ritchey & Goeke, 2006) for the remediation of difficulties in efficient sound-symbol processing. Other approaches include 1) whole language (reinforcing a spectrum of language arts), 2) thematics (utilizing content areas conceptually), 3) literature-based methods (using trade books to build on basal program skills), 4) individualized reading programs (using trade books and alternative literature forms to build personal reading), 5) language experience (having students generate their own reading material), and 6) functional skills (involving the use of materials involved in daily living, e.g., forms, notices, and directions). The increased influence of STEM (science, technology, engineering, and math) has broadened the application of reading and writing skills across the content domains. Unfortunately, teacher preparation programs may not be providing content area teachers with a broad enough understanding of specific learning disabilities and the tools to modify instruction to meet these students' needs.

Despite this, teachers at all levels and in all types of classrooms can give students with SRD tools such as 1) graphic organizers (a visual representation of the material a student is learning that assists the student in brainstorming and/or organizing information to make it easier to understand how ideas connect), 2) anticipation guides (study guides that prepare students to identify the major themes and concepts of a written work,

3) question/answer strategies, 4) think-alouds (explicit modeling in which teachers give an oral description of the cognitive processes they go through as they read with their students), 5) charting and outlining, and 6) induced imagery (teacher guided mental imagery while reading to enhance comprehension). These schemata all help students retain the messages they get through their reading. The intent of these strategies is to provide the reader with ways to chunk or otherwise partition their reading material into segments that they can better understand. The goal of such instructional interventions is movement toward higher levels of critical thinking. By attaining these skills, the student can compete with peers in academic tasks that connect reading to other skills, such as writing and oral discussion.

Reading in Middle School and High School

The mandates of No Child Left Behind, as well as the requirements of school districts for the acquisition of credits toward graduation, have raised the bar for the attainment of a diploma. In addition, a diploma is not acquired by passing courses alone. High school students must demonstrate the ability to pass statewide-standardized measures of mastery of core subjects as well. The path toward independent adulthood, higher education, and continued training in skills needed for employment has a distinct “turn” as students move into middle school and then into high school. As previously stated, in December, 2015, NCLB was replaced by the Every Student Succeeds Act. Although the original provisions of NCLB remain for many aspects of assessment, much of the change relates to the shift of responsibility and accountability for student performance to the individual states. States must show that they have adopted challenging standards in reading, math, and science and that the levels of achievement comport with the standards for admission to higher education institutions as well as with the standards in career and technical education. States may develop alternative assessment standards for students with the most significant cognitive disabilities, but the number of students determined to qualify for this accommodation is limited. In addition, states may choose to administer assessments in annual or multiple interim formats.

The demands of middle school and the pressures of high school programs can be very trying for students with learning disorders. As individuals move from the structure of elementary school to middle and high school, the demands of content reading become an additional burden. The discrete skills of content reading and the related study skills needed for success in secondary education are divided into two approaches. One is a direct instructional approach that separates skills from content, and the other is a functional

approach that embeds reading and study skills into the content.

In middle and high school, the reading process must connect with other skills needed for mastering content-related matter in subjects such as social studies, geography, higher level mathematics, and sciences. Study, organizational, and problem-solving skills must blend with the processing skills involved in obtaining meaning from words, sentences, charts, maps, books, poetry, and dramatic or narrative literature. Meaning is easier to teach in the elementary and middle grades than in high school, when it may become buried in nuances of language, such as humor, sarcasm, and metaphor.

The expertise of general educators in middle and high schools is in the content they teach and not in the instructional mechanisms that help students organize, retrieve, and explain text related to that content. In addition, secondary school requires learning multiple content areas in discrete settings with several different teachers. Consequently, the student with SRD may become a “cumulative deficit” reader who makes progress but at a rate that is too slow to maintain adequate academic achievement. The content teacher, therefore, needs to understand not only the demands and organization of his or her content, but also how students must organize that content from lessons so that they can use it in the many forms that secondary school demands (e.g., exams, research papers, and debates).

Writing As much as reading dominates the instructional day of students with SRD, students with disorders of written expression (e.g., dysgraphia) have specific disabilities in processing and reporting information in written form. Writing is firmly connected to reading and spelling because comprehension and exposition of these skills are demonstrated through production of written symbols as indicators of understanding (Berninger & Wolf, 2009; Mason & Graham, 2008). Although writing is a representation of oral language, it also must convey meaning without the benefit of vocal intonation or stress. This makes additional demands on the writer.

Problems in writing may result from either an inability to manipulate a pen and paper to produce a legible representation of ideas or an inability to express oneself on paper. Word processors can assist individuals who have disabilities related to the manipulation of the writing implements (Bain, Baillett, & Moats, 2001; MacArthur, 2009). Remedial and instructional techniques that are helpful with problems of written expression include the use of 1) open-ended sentences; 2) probable passages (a strategy used to draw on a student's prior knowledge of a topic while incorporating

writing into a basic reading lesson); 3) journal keeping; 4) modified writing systems, using rebuses in which words are represented by combinations of pictures and individual letters or other symbols; and 5) newspapers and other print media to demonstrate various writing styles and organizational models. Additionally, the ability of the student to maintain and self-regulate attention to spoken and print language sources has an impact on the development of writing and its connection to executive functions (Berninger, Abbot, & Cook, 2017).

Not to be forgotten is the connection of spelling to writing. The developmental stages of spelling need to be explored as teachers approach instruction that connects what is read to the written response of students. These stages include prephonemic, phonemic, transitional, and conventional spelling (Bear & Templeton, 1998). In 1998, the International Reading Association and the National Association for the Education of Young Children (1998) issued a joint position statement that advocated a developmental approach to teaching writing as an outgrowth of the reading process, recommending that students should be moved from the initial, prephonemic, and phonemic attempts at spelling toward correct, conventional spelling of English words. The process must reflect an understanding of the developmental level and needs of the individual student as well.

Content area literacy calls for connections between reading and writing and the development of study skills and organization of written materials so that they are retrievable for later use. Interventions in this area may call for students to share their writing with peers and to examine the writing styles of others. Among the research-based strategies that assist the student with writing disabilities is self-regulated strategy development, a six-step cognitive strategy model designed to make the writing process complete, automatic, and flexible for all subjects (Graham & Harris, 1989; Harris & Pressley, 1991; Reid, 2005; Berninger, Abbott & Cook, 2017).

Writing is also a sociocultural endeavor, representing a cognitive process learned through dialogic interactions, expressing the social and cultural perspectives of the student (Englert, 1992). The difficulties that a student with a learning disorder may have with social perception and awareness of cultural aspects of personal development may influence the written product as well as the writing process.

Mathematics Students with a math disability (i.e., dyscalculia) have an impaired ability to perform basic math operations (i.e., addition, subtraction, multiplication, and division) or may have trouble applying

those operations to daily situations (Mazzocco, 2007; Raghubar et al., 2009). Often, however, the problem is in understanding the abstract concepts of mathematical usage (Mabbott & Bisanz, 2008). When students with dyscalculia have only written math problems to solve, the concepts remain vague. When functional applications (e.g., involving money or time) and manipulatives are used, however, the student can connect the concepts to their practical applications and demonstrate greater understanding. For some individuals with this disorder, a calculator may prove helpful. Thus, teaching may focus on the use of money in fast food restaurants (e.g., making change), grocery shopping (e.g., comparing prices per unit of weight), banking (e.g., balancing a checkbook or calculating interest), cooking (e.g., measurement), and transportation (e.g., reading directions and maps and keeping to schedules).

The language aspects of instructing students with a math disability, especially those who also have SRD, have been studied to determine how the reading process influences performance in numeric problem solving (Andersson & Lyxell, 2007; Fuchs & Fuchs, 2002; Powell, Fuchs, Fuchs, Cirino, & Fletcher, 2009; Peng & Fuchs, 2016). In these studies, for students with both reading and math disabilities, problems requiring addition were easier to solve than problems requiring subtraction or problems requiring making change. Powell and colleagues (2009) investigated how much the format of word problems connects to numeric ability and discovered that students with math disability demonstrated an improved ability to solve word problems in math by using diagramming as an intervention (Van Garderen, 2007) to incorporate visuo-spatial reasoning.

The importance of adequate assessment tools in the determination of math disability has been discussed by Lembke and Foegen (2009), whose research in early numeracy (the ability to understand and work with numbers) has posited the relationship of number sense to phonemic awareness in reading. As indicators of math performance among primary grade students, they have identified the skills of quantity discrimination, number identification, and missing number identification as three strong predictors of early mathematical success. Assessment and determination of the possibility of other disabling conditions that might affect learning has also been a concern for researchers, especially the combined impact of reading and math disabilities (Dirks et al., 2008). Limited study has been done on this combined disability effect, although Dirks and colleagues have estimated that more than 7% of students have both SRD and math disabilities.

Powell and colleagues (2009) have demonstrated the effectiveness of an approach that emphasizes problem type for solving mathematical word problems

and complex operations (e.g., multiplication). Another approach, emphasizing executive function, involves rehearsal, practice, and mastery of math skills in combination with corrective and positive feedback throughout the process of instruction. A metacognitive approach can give students with dyscalculia hope for greater success and facility in progressing to higher and more complex mathematical operations (Desoete, Roeyers, & Buysse, 2001; Keeler & Swanson, 2001).

The concepts, principles, and procedures that are part of mathematics instruction increase in difficulty through the grades, and so the identification of a math disability may follow the student throughout his or her school career. Geary and Hoard (2005) described the executive functions that are disrupted, namely regulation of attention and the ability to distinguish between relevant and irrelevant numeric associations in solving problems.

For many students with mathematical disabilities, the more abstract levels of mathematics, such as algebra, geometry, and calculus, may remain mysteries forever; however, these students can still gain facility with basic mathematical facts used in daily life (Mercer & Pullen, 2004). Many schools teach students how and when to use calculators so that more complex problems can be simplified or homework checked for accuracy. In addition, computer-assisted instruction in mathematics may provide opportunities for practice and reinforcement.

Other Interventions

Training in Social Cognition The maintenance of self-esteem and the development of social cognition are very important in preventing adverse mental health outcomes in any child. Bandura's (2001) research on social-cognitive theory and self-efficacy has had its impact on general education, but relatively little research has been done on at-risk groups of students, which would include those with learning disabilities. Social and emotional competence is impacted by personal and interpersonal agency, and it influences the outcomes of well-being in these children (Martin, Cumming, O'Neil, & Strnadova, 2017).

Counseling Counseling may be required to treat underlying mental health issues in children with a learning disorder. This can be provided individually or in groups. Family-centered counseling also may be appropriate. Issues to be discussed may include homework, behavior management techniques, parental expectations, and the child's self-esteem. Families also should be provided a source of information about learning

disorders, support groups, and their legal rights and responsibilities in the education of their child. In addition to support for families as they get help for their child with learning disorders, these families, especially parents, may need help in addressing their own feelings of grief or powerlessness in assisting their child toward independence in adulthood, higher education, and employment. Innovative therapeutic interventions include movement and dance therapy, art therapy, and music therapy (Unkovich, Butte, & Butler, 2017).

Medication Although learning disorders cannot be "cured" through the use of medication, certain associated impairments that affect learning, such as ADHD (see Chapter 19) and behavior and emotional disorders (see Chapter 27), can be improved with the use of psychoactive drugs. If such drugs are used, their effectiveness must be monitored carefully. Medication should never be a substitute for sound educational programming (see Chapter 38 for a detailed discussion of the role of medications in the treatment of developmental disabilities).

Homework The home and school should be able to function in partnership so that homework does not lead to tension among family members or misunderstanding of the teacher's intent in providing the home assignment. This may require assisting the parent in setting up a workable system and schedule at home. Students with learning disorders often feel that homework is an imposition, providing no personal fulfillment or advancement, so individualization and creative use of assignments is essential for homework to fulfill its reinforcing purpose. Homework should supplement material that was taught during the day (Alvermann & Phelps, 2005).

The improvements and availability of technology to support students in completing assignments have been shown to assist homework completion, especially at the middle and high school levels (King-Sears, Evmenova, & Johnson, 2017). Techniques to facilitate homework performance include the use of coaching models as well as traditional models of home completion. There does not seem to be one particular system of doing homework that emerges as most effective, but research does indicate that the student's perception of the usefulness of the assignment is important (Merriam, Coddington, Tryon, & Minami, 2016). There are non-academic effects of homework on student perceptions of well-being and behavior, particularly for students in high-achieving school settings (Galloway, Conner, & Pope, 2013). Homework should be limited to a specific time allotment. Since 2006, the National Education

Association has recommended 10–20 minutes per day for individuals in kindergarten through second grade and 30–60 minutes per day for individuals in Grades 3–6. Ideally, homework should be completed in a specific area of the home that is quiet, organized, and stocked with needed supplies. Children with learning disabilities may also not bring homework assignments home either to avoid doing them or because they lack the organizational skills to remember the assignment. Many tools are available to assist with this process, including day planners, checklists, iPads, or other technologies. Some schools post homework assignments on the Internet or through other electronic methods—these should assist families in knowing the schedule and content of assignments.

Periodic Reevaluations

The treatment programs for students with learning disabilities are complex, and many potential gaps exist. Furthermore, the child is continually developing, with needs and abilities that change from year to year. Therefore, ongoing monitoring of school progress is essential. The goal of periodic reassessments is to evaluate academic progress, psychosocial issues, and parent–child relationships. Reassessment is also an opportunity to convey new information to the family in an effort to obtain appropriate resources. Finally, it is a time for reassessing the child and revising the educational program. These reevaluations should occur ideally on a yearly basis so that planning for the next school year can occur. Parents and school providers need to be familiar with federal and state policy and regulation on the schedule of assessment and reassessment in order to properly serve the student with learning disabilities as they respond to varied interventions (Silbergitt, Parker, & Muyskens, 2016).

OUTCOME

Academic preparation and interventions have allowed more and more students with SLDs to pursue postsecondary education and to find success in the workplace.

Postsecondary Education

The National Center for Learning Disabilities notes that 68% of high school students with SLD exit with a diploma, compared to 12% who graduate with a certificate of attendance. Unfortunately, they also report that 19% of these students drop out of school before graduating (National Center for Learning Disabilities,

2017). Academic preparation of students with learning disorders is permitting more and more students to pursue postsecondary education. However, having an average of a 10th-grade reading level (Hughes & Smith, 1990; Mason & Mason, 2005) confounds the student with learning disabilities as they attempt the spectrum of academic challenges at the college level. These challenges include writing essays and research papers, completing long and complex reading assignments, taking timed tests, and learning foreign languages (Denckla, 1993; Duquette & Fullarton, 2009; Murray & Wren, 2003).

Some colleges offer adjustments to program loads and schedules, tutorial and other support services, and support technologies that have permitted students with learning disorders to complete college at an increasing rate (Jones, Long, & Finlay, 2007). Among the problems encountered by students with SLD as they enter college is the fact that only 25% identify their special needs to the college, therefore diluting the impact of accommodation or support that may be available. If such accommodations are not obtained early in the postsecondary experience, the risk of not graduating is greatly increased. The completion rate for students with SLD is 41%, compared with a completion rate of 52% for the general population (National Center for Learning Disabilities, 2017).

Employment

Career direction and preparation should be an objective of educational programming beginning in the primary grades. Such training for students with learning disabilities begins with realistic goal setting resulting from a comprehensive assessment of abilities and aptitudes. Without appropriately directed training, students may be unable to support themselves in an independent manner as adults. If career preparation and training services are delayed until adulthood, they are less likely to be effective. The design of these programs becomes part of the student's IEP (see Chapter 33).

A generation ago, the U.S. Department of Labor (1992) published competencies determined to be necessary for employment. This report by the Secretary's Commission on Achieving Necessary Skills (known as the SCANS Report) translated into curriculum areas that deemphasized specific job-related tasks in favor of teaching general competencies that cross all job markets.

Even as adults, some individuals with learning disorders have poor retention of verbal instructions and other problems that may interfere with effectiveness in

their jobs. They also may be hesitant to ask questions and seek assistance. Social immaturity, clumsiness, and poor judgment may make social interactions more difficult. The skills taught in career education are those required to overcome these impairments and enhance success in the work environment, be it the classroom or the adult job market. Cooperation, respect, responsibility, teamwork, organization, and ways to seek information to solve one's problems are all part of career education (U.S. Department of Labor, 1992).

According to the National Center for Learning Disabilities report mentioned above, over 46% of students with learning disabilities hold jobs in competitive employment situations. This cannot be judged too critically, however, in light of national trends in employment that might be influenced by economic downturns that affect all potential workers leaving high school. The Bureau of Labor Statistics reports that in 2017 the unemployment rate was 4.8% nationally; however, the unemployment rate for those with a college degree was only 2.5%, while those without a college degree was over 7%. This figure is much increased for young adults with learning disabilities.

SUMMARY

- A specific learning disability is a developmental disorder in which a healthy child of average to above-average intelligence fails to learn adequately in one or more school subjects.
- The underlying cause of these disorders is aberrant brain function, such as impaired phonological decoding in specific reading disability. Neuroimaging, genetic, and neuropsychological studies are providing insight into how the brain guides learning.
- Early detection of learning disorders is important because, if untreated, the child may develop secondary emotional and behavior problems that hinder progress.
- If a learning disorder is suspected, a psychoeducational evaluation should be performed to identify areas of strengths and challenge. Then the education team can develop an individualized education program and appropriate changes in curriculum and supports can be made.
- No single treatment method is ideal for all individuals, so an empiric approach may be needed to find the most useful method. Studies also suggest that the amount of time spent in remediation/practice is very important.
- Career and vocational education should be included in the general educational curriculum and as an individualized transition plan within the IEP.
- Although the individual with SLD usually carries his or her learning impairment into adulthood, the outcome is often good.
